The mortality statistics in the table relate to the deaths of civilians actually belonging to the several boroughs, the deaths occurring in institutions having been distributed among the boroughs in which the deceased persons had previously resided. During the four weeks ended Feb. 26th the deaths of 4850 London residents were registered, equal to an annual rate of 14·0 per 1000; in the three preceding months the rates had been 13·1, 14·2, and 12·5 per 1000. The death-rates ranged from 11·6 in Camberwell and in Woolwich, 11·8 in Deptford, 12·2 in Wandsworth, and 12·9 in Lambeth, to 16·7 in Bethnal Green, 16·8 in Holborn, 17·1 the City of London, 17·2 in Chelsea, and 18·7 in Kensington. The 4850 deaths from all causes included 250 deaths which were referred to the principal infectious diseases; of these, 7 resulted from measles, 28 from scarlet fever, 92 from diphtheria, 43 from whooping-cough, 1 from enteric fever, and 79 from diarrhœa and enteritis among children under 2 years of age. No death from any of these diseases was recorded in the City of London. Among the metropolitan boroughs the lowest death-rates from these diseases were recorded in Paddington, the City of Westminster, Hampstead, Hackney, and Lewisham; and the highest in Kensington, Stoke Newington, Shoreditch, Bethnal Green, Bermondsey, Battersea, and Wandsworth. The 7 deaths from measles were only one-sixteenth of the average number in the corresponding period of the five preceding years; of these, 4 belonged to Stepney and 2 to Islington. The 28 fatal cases of scarlet fever exceeded the average by 13; of these, 3 belonged to Bethnal Green, 3 to Wandsworth, and 3 to Woolwich. The 92 deaths from diphtheria exceeded the average number by 24; the greatest proportional mortality from this disease occurred in St. Pancras, Stoke Newington, Poplar, Bermondsey, Battersea, Wandsworth, and Greenwich. The 43 fatal cases of whooping-cough were 70 fewer than the average; of these, 8 belonged to Islington, 5 to Kensington, 4 to Southwark, and 3 each to Lambeth, Battersea, and Wandsworth. One death from enteric fever was registered during the month, against an average of 4. The 79 fatal cases of infantile diarrhœa were 13 in excess of the average number; the greatest proportional mortality from this disease occurred in Chelsea, Shoreditch, Bethnal Green, Southwark, Bermondsey, and Battersea. In conclusion, it may be stated that the aggregate mortality in London during February from these principal infectious diseases was 34 per cent. below the average in the corresponding period of the five preceding years.

ANALYSIS OF SICKNESS AND MORTALITY STATISTICS IN LONDON DURING FEBRUARY, 1921.

(*Specially compiled for* THE LANCET.)

Cities and Boroughs.	Estimated civil population, 1920.	Notified Cases of Infectious Disease.												Deaths from Principal Infectious Diseases.									Deaths from all causes.	*Death-rate per 1000 living.*
		Small-pox.	Scarlet fever.	Diphtheria.*	Typhus fever.	Enteric fever.	Other continued fevers.	Puerperal fever.	Erysipelas.	Cerebro-spinal meningitis.	Poliomyelitis.	Total.	Annual rate per 1000 persons living.	Small-pox.	Measles.	Scarlet fever.	Diphtheria.*	Whooping-cough.	Enteric fever.	Diarrhœa and enteritis (under 2 years).	Total.	Annual rate per 1000 persons living.

* Including membranous croup.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Increase of Prostitution and Syphilis in Vienna during the War.

IN a recent report of the Board of Health interesting data are given as to the part played by lues in the mortality statistics of this city. From 1911 to 1920 a total of 1125 cases observed post mortem in Vienna were strictly due to syphilis; gummatous conditions and congenital or other absolutely sure manifestations were considered proof of syphilitic causation of death. In 1911 114 cases were classified as belonging to this group; the figures for the years till 1918 were respectively 107, 109, 147, 97, 91, 90, 79. In 1919 a sudden rise to 129 occurred, increased in 1920 to 162. During the years 1909–19 78 per cent. of these deaths from syphilis occurred amongst infants under 1 year old. From 1914 to 1918 the falling birth-rate was accompanied by a marked drop in deaths from syphilis; but in 1919 the birth-rate went up only 25 per cent., as compared with the previous year, whilst deaths from syphilis were increased by 63 per cent., and in 1920 the birth-rate rose 35 per cent., and the syphilis death-rate rose more than 100 per cent. over the 1918 figures. The children born in 1919 and 1920 have thus suffered very severely; this fact is not surprising, since nearly every healthy man between the ages 19 and 50 had been called to the front during the years of war. Complementary information is given by reports of the sanitary department of the police in Vienna. It is the function of this department to control both the declared and the clandestine prostitutes. By surprise visits to hotels, &c., and by control of the streets, such women are supervised and subjected to exact examination, when those found to be ill or infectious are at once taken to hospital. Thus in 1918, of 5540 females examined 27 per cent. had to be sent to hospitals; in 1919, of 6666 examined 25·4 per cent. were diseased; in 1920, 7240, 29 per cent. diseased. More than 60 per cent. of these women are below 24 years of age, and fully 20 per cent. of the total are under 18 years. These young girls have little or no knowledge of self-protective hygiene, and quickly fall victims to venereal infection. More than 50 per cent. of them were found infected, whilst of the older prostitutes about 22 per cent. needed immediate treatment. In a large number of cases the motives for taking up this "career" were noted; poverty, hunger, and the desire for fine clothing were responsible in about half the cases investigated, whilst moral depravity, bad example, or lack of proper supervision and care accounted for the other half.

A Rare Case of Torsion of the Entire Omentum.

At a recent meeting of the Medical Society of Vienna Dr. Hirsch demonstrated a rare specimen obtained a few days ago by operation on a medical man. The patient had been suffering from inguinal hernia for a long while. He had always succeeded in retaining the hernia by means of a pad, but it had for a long while been troublesome. On the day before operation the reposition of the hernia, which had again caused trouble, was impossible, and serious symptoms with pain set in. A diagnosis of incarcerated hernia was made and operation performed immediately. On incising the hernial sac it was found empty, except for some liquid. It was therefore clear that the surgeon had acted upon a wrong diagnosis. Laparotomy was then performed; the abdomen being opened, a large purplish tumour appeared, which was soon discovered to be the omentum majus, turned on its own axis three times 360°. The pedicle was as thick as a man's forearm. Total ablation of the tumour had to be performed, and the patient made an uninterrupted recovery. Cases of torsion of the entire omentum are sufficiently rare to justify record of them, and only in a very few instances has a correct diagnosis been made before operation. The mechanism of the condition is that the appendices loicæ become lodged in an existing hernial sac, and subject to traumatism by a pad and by repeated handling, reposition, or other manipulations; they then grow thicker and heavier and stretch, causing a torsion of parts and, in suitable cases, of the entire omentum. The pathological changes taking place in the tissues are so rapid in their onset that it is hardly possible to do anything less than to remove the entire strangulated portion of the organ even after a short duration of the condition.

Renewal of Dispute Between Medical Dentists and Dental Mechanics.

In July, 1920, a Bill passed the National Assembly in Vienna, which regulated the relations between medical dentists and dental mechanics in a way thought at that time to be satisfactory to all parties concerned. It was the result of a compromise, arrived at by coöperation of the representatives of the profession and of the dental mechanics. Its chief features were the following: (1) All persons being at the time of the commencement of the Act engaged in dentistry, either as mechanics or as medical dentists, are entitled to practise their profession without restriction, except that purely surgical interferences were permitted only to the medical dentists, extraction of teeth being regarded as a surgical interference. (2) The occupation of dental mechanic should gradually die out as an independent vocation by the fact that no new licence should be given except to a medical dentist—i.e., a doctor of medicine. (3) The mechanic should in future be only an assistant of the doctor, except those 650 men who at present had offices of their own and worked both for the doctors and their own patients. This understanding, however, was not long in force. The mechanics are not satisfied with permission to excavate and fill the teeth besides making the mechanical appliances and prostheses. They now want also to be entitled to perform surgical operations, extractions—in fact, to be regarded as perfectly equal in their rights to the medical dentists. Opposition to their demands has been answered by a mechanics' strike. The mechanics' organisation has caused all apprentices and assistants to the medical dentists to resign their offices, and has offered them employment with the practising mechanics. The medical profession are endeavouring to settle the problem by enlightening the public on the dangers and risks offered by such a state of affairs, but adhere to the opinion that it is the duty of the Government to make the mechanics obey a law passed only half a year ago with their active consent.

Increase of Rickets in Austria.

One of the chief evils derived from malnutrition is the spread of rickets amongst Austrian children. The Board of Health has tried to obtain reliable data as to the frequency of this condition, but returns cannot be obtained from many rural districts; and large numbers of peasant families never summon a medical man. Investigators had therefore to be content with the fact that only the severer cases were reported. Rickets has without a doubt become much more frequent during and after the war, especially amongst children over 12 years old. In 1913, 5 principal children's hospitals showed on their books 640 cases of rickets; in 1919 the figure stood at 2859, amongst them 589 over 12 years of age. The lack of milk, of fats, and farinaceous food was especially felt amongst the poorer classes. Amongst infants the increase of rickets was not so much marked, for breast-feeding was more often resorted to, owing to lack of other food for the babies. The frequent appearance of rickets amongst older children (above 12) seems to be analogous to the frequency of osteomalacia amongst adults in these times.

Results of Examination of School Children by School Doctors.

Interesting facts were ascertained at a recent meeting of school doctors about the pathological conditions found amongst school children in rural districts. In one of our most cultivated country towns 330 boys and 310 girls were examined, all 6 years of age, just at entering school. Their average weight was: boys 19 kilos, girls 18·66 kilos; height: boys 111½ cm., girls 110; circumference at nipple of breast: boys

58½ cm., girls 56·75. The following conditions were found to be present: Adenoids in 20 boys and 7 girls; swollen glands, 103 cases each; 30 boys and 18 girls had rickets; 7 children had organic heart disease; 12 boys and 35 girls suffered from goitre; 9 boys and 14 girls from myopia; 6 boys and 2 girls had herniæ; 39 boys and 27 girls had an apical lesion with a negative Pirquet test; whilst only 3 each had positive Pirquet. Enlarged tonsils were found in 34 boys and 19 girls, 4 boys and 16 girls were deaf, whilst 12 boys and 27 girls had scoliotic changes and 7 boys were hydrocephalic. The number of backward cases amongst older school children was found sufficiently large to justify the establishing of special classes for them. It appears to be necessary very early to pay special attention to defects of the vertebral column; faulty sitting in school is not so much to blame for scoliosis or flat breast, but an organic change, manifest already in very early life. Gymnastics are required to control such conditions. Also myopia and deafness are often the result of a previous disease or disposition, and not necessarily only due to the traumatism of school teaching. Glands in children are only of importance if they appear in the supraclavicular region—mostly associated with pathological changes in the apices of the lungs.

March 9th.

The Services.

ADDITIONAL PAY FOR OFFICERS ON COMMITTEES.

AN Army Order provides that a field officer on full pay who is appointed to serve on a committee or to act as its secretary in virtue of possessing special scientific knowledge not acquired as part of his normal military duties will receive 15s. of additional pay for each day on which such committee sits. A captain or subaltern serving in similar circumstances will have additional pay of 10s. a day.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Col. E. A. Bourke is placed on retired pay on account of ill-health contracted on active service.

Temporary Captains relinquishing their commissions and retaining the rank of Captain: J. Anastasi and A. G. Wright.

TERRITORIAL FORCE.

Lieut.-Col. J. H. Harris, T.D., resigns his commission and retains the rank of Lieutenant-Colonel, with permission to wear the prescribed uniform.

Capt. P. J. Gaffikin to be Major.

Capt. and Bt. Major R. E. Barnsley, R.A.M.C., to be Adjutant of the R.A.M.C. School of Instruction, Northern Division (T.F.).

Lieut.-Col. A. B. Lyon is appointed to command 1st London Casualty Clearing Station.

Major J. R. Benson resigns his commission and is granted the rank of Lieutenant-Colonel.

Major A. W. French and Capt. W. T. P. Meade-King resign their commissions and are granted the rank of Major.

Major A. G. Roper resigns his commission and retains the rank of Major.

Capt. (Bt. Major) E. G. Smith resigns his commission and retains his rank.

Captains resigning their commissions and retaining the rank of Captain: C. F. Backhouse, A. J. H. Iles, S. L. Brimblecombe, C. E. M. Jones, C. H. Maskew, A. V. Maybury, C. F. Glinn, G. C. F. Robinson, B. Dyball, R. V. Solly, R. Jaques, H. Andrew, C. D. Lindsey, W. L. Pethybridge, J. L. Wright, C. Lamplough, J. E. F. Palser, A. W. Power, M. H. Way, and C. H. Saunders.

4th Southern General Hospital: Lieut.-Col. J. E. Square resigns his commission and retains the rank of Lieutenant-Colonel. Major (Bt. Lieut.-Col.) J. W. Gill resigns his commission and retains his rank.

5th Southern General Hospital: Major N. E. Aldridge resigns his commission and retains the rank of Major.

TERRITORIAL FORCE RESERVE.

Lieut.-Col. C. A. Lees, from 2nd London (County of London) General Hospital, to be Lieutenant-Colonel.

LITERARY INTELLIGENCE.—Messrs. W. B. Saunders Company announce for early publication Keen's "Surgery," volumes seven and eight, which will complete the work.—The Williams and Wilkins Company, of Baltimore, U.S.A., announce the early appearance of the first number of the new *American Journal of Tropical Medicine*, of which the annual subscription price, net postpaid, to British subscribers is 23s. The journal, which will appear six times a year, is edited by Dr. H. J. Nichols, Major, U.S.M.C., Army Medical School, Washington, D.C.

Correspondence.

"Audi alteram partem."

VANISHING TYPHOID IN PHILADELPHIA.

To the Editor of THE LANCET.

SIR,—Thirty years ago Philadelphia had a death-rate from typhoid fever of 63·9 per 100,000 inhabitants. Last year it was 3·3 per 100,000. The reason is—filtered water. Just how consistently the fall occurred during the installation of the filtration system is well worth noting. This system was commenced in 1899, was completed in 1912, and cost about 28 million dollars. It has been estimated that if the same rate of mortality had held in 1920 as averaged from 1898 to 1908 there would have been 900 deaths and about 6000 prostrated from typhoid; instead of this the total deaths in the entire city were 60, and almost one-half of these were traceable to outside sources of infection. Considering the population of 1,837,924 on July 1st, 1920, this is a wonderful showing. Philadelphia is certainly trying to answer the historic question: If preventable, why not prevented? During the period 1862–1870 there occurred the very high average of 79·9 per 100,000; the next decade showed 58·1 and the rate of 45·2 in 1901 to 1910 suddenly broke to 12·5 in 1912, when all the water was filtered. The recent years show the following rates: In 1914 the rate was 7·5; in 1917 it was 6·2; in 1918 it was 4·8; in 1919 it was 4·4; and in 1920 it was 3·3. Incidentally the death-rate from diarrhœa and enteritis has fallen 40 per cent. in eight years and the mortality of children under 1 year 20 per cent.

Philadelphia takes her water-supply partly from the Delaware river and partly from the Schuylkill river. Higher up on both these rivers are active manufacturing cities such as Trenton and Norristown, but the problem seems to have been solved to render the water pure notwithstanding this handicap. When the filtered water was first sterilised it was accomplished by the use of hypochlorite of lime; but since 1914 liquid chlorine has supplanted the hypochlorite, and is applied as required to the effluents of all filter stations. The quantity of liquid chlorine is determined by results of daily analyses of effluents. Thus Philadelphia fortunately provides for all its inhabitants water that is sterilised after filtration. I am, Sir, yours faithfully,

GUY HINSDALE, M.D.

Hot Springs, Virginia, March 12th, 1921.

*** Dr. Hinsdale's letter provides a pendant to the annotation on water-borne typhoid in our issue of March 12th.—ED. L.

GRAVES'S DISEASE.

To the Editor of THE LANCET.

SIR,—In the recent discussion on Graves's disease at the Royal Society of Medicine, reported in recent issues of THE LANCET, it seems strange that so little was said as to the danger of removing, or interfering with the blood-supply to, the parathyroid glands, for it is a very real risk. Sir William Stokes removed one-half of an enlarged thyroid from a girl of 18 years; the case did well; three and a half months later he removed the remaining half; in 11 days there occurred mental torpidity, slowness of speech, swelling of eyelids, face, and hands, and also dilatation of pupils, disturbances of respiration, and rapidity of pulse and death occurring 21 days after operation. There is little doubt that the latter group of symptoms and the fatal termination were due to the removal of the parathyroids. It is clear that in partial operations the complication is rare, and it seems natural to think that the best operation in Graves's disease would be, as Crotti recommends, to remove the front part of both lobes and the isthmus, avoiding the back part of the lobes where the parathyroids and recurrent laryngeal nerves lie; the number and distribution of the parathyroids and the danger cannot be wholly avoided; we therefore indebted to Dr. W. S. Halsted for informing us how to recognise and treat the symptoms. A patient under his care on the eighth day after a thyroid operation had several attacks of numbness commencing in the lips and extending to the face and arms. The patient said the attacks were indescribably awful and that she would sooner die than have many more of them. Dr. Halsted was so confident of the cause of the symptoms that he immediately sent to Dr. W. G. MacCallum for dried parathyroids of beeves; the effect of parathyroid exhibition was almost instantaneous and most marvellous; it is stated that an equally good result can be obtained by the administration of calcium salts. In experiments on the lower animals in which the parathyroids have been removed, in a minority of cases the animals can be kept alive for weeks and months and even years by putting them on a diet consisting solely of milk. This is the best way to exhibit calcium, for 10 gr. of the lactate of calcium only corresponds to 2 oz. of milk, which would probably have no effect. Equally good results, it is said, can be obtained by the salts of strontium, and also by those of magnesium and barium, but as these last two are poisonous they cannot be used; thus there are three specific remedies for aparathyroidea—namely, parathyroids and the salts of calcium and strontium.

It is said there is no specific treatment for Graves's disease, but Dr. Lockhart Gillespie cured three children of about the age of 10 years by giving them each 10 gr. of the iodide and 5 gr. of the bromide of strontium three times a day, in 33, 21, and 30 days respectively.[1] Further, we cannot be sure that the improvement which occurs in cases of Graves's disease when kept in bed and fed on a diet into which milk enters largely is not due in part to the specific action of the calcium in the milk.

There is a connexion between Graves's disease and diabetes; it is therefore interesting to note that Dr. A. S. Donkin, in a farmer with diabetes, by placing him on a diet solely of skimmed milk in 16 days, reduced the amount of sugar in the urine from 25 gr. to the ounce to nil, and this notwithstanding the large amount of sugar in 8 pints of skimmed milk.

I am, Sir, yours faithfully,
WALTER EDMUNDS.

Carlton-road, Putney, S.W., March 19th, 1921.

THE PATHOLOGY OF RELAPSING FEVER.

To the Editor of THE LANCET.

SIR,—In an account of the discussion following Lieutenant-Colonel J. C. Kennedy's paper on this subject, read at the Royal Society of Tropical Medicine and Hygiene and published in THE LANCET on March 12th, I am quoted as having said with reference to relapsing fever in Mesopotamia "the case mortality among Arabs was 8 per cent., among Indians 1 per cent., &c." The figures given by me related to a series of cases in 1917 and 1918, and were: "The case mortality among Indians was 8 per cent., among Arabs 1 per cent., &c." I am, Sir, yours faithfully,
W. H. WILLCOX.

Welbeck-street, Cavendish-square, W., March 21st, 1921.

VENEREAL INFECTION IN RHINE ARMY.

To the Editor of THE LANCET.

SIR,—I have always found the War Office records regarding venereal disease to be kept most accurately and stated (for public consumption) most confusingly. What we want to know is: (1) What is the V.D. contraction rate for each month, calculated at the rate per 1000 per annum for the Rhine Army, from Jan. 1st, 1919, to Jan. 31st, 1921? (2) What is the average strength of the Rhine Army and the average number of V.D. cases under treatment in hospital or otherwise?

To show how the same facts may be presented in a most misleading manner let me set out the following: On p. 111 of Dr. E. B. Turner's evidence before the National Birth-Rate Commission (Special Enquiry) in November last:—

> "In Cologne the numbers varied, hovering about 12,000 men. When I was there the 25th General Hospital, Venereal Disease, with 500 beds, was full, and in addition there were those who were being treated at E.T. centres for mild cases."

And Dr. Turner also told the Commission (I was present at the time) that there was a "waiting list" of V.D. patients. Now if the number of cases actually under treatment, in hospital or otherwise, was 600 for 12,000 troops that would be a rate of (for hospital, plus, say, 100 E.T. cases) *500* per 1000 per annum. This is not an unbelievable rate, because the American Forces in Paris had for January, 1918, a rate of *480* per 1000 per annum. That fact is stated by Lieutenant J. E. Moor,[1] who was the M.O. i/c of the American Medical Report Centre, Paris District. Then disinfection was thoroughly applied, some 72 prophylactic stations being ultimately established, and enormous quantities of calomel tubes were distributed officially and unofficially, and the rate at the end of 1918 for the American forces in Paris district had dropped to *94·6* per 1000 per annum, a great tribute to the American medical officers and the American Red Cross, hampered as they were by public ignorance and mistaken opposition. Later they were misguided also by certain English officials, and began to rely only on depôt disinfection, and hence in the beginning of 1919 their rate had risen to *148* per 1000 per annum. The rate for all troops in U.S.A. (with depôt disinfection) for six months ending Dec. 27th, 1918, was *150·62* per 1000 per annum, and the rate given in the National Birth-Rate Commission's report for American troops on the Rhine in 1920 averages *142* per 1000 per annum.

Now what is the rate for the British Army on the Rhine? Dr. Turner's figures work out at 500 per 1000 per annum. Sir Archdall Reid, giving evidence in the same place, suggested the rate was from 200 to 250 per 1000 per annum, and we have the following official statements:—

> 1. "The records show that in our Army on the Rhine, which numbers from 11,000 to 12,000 men, the percentage of troops suffering from V.D. is 2·6."—*Evening Standard*, March 6th, 1921.
>
> 2. Sir L. Worthington-Evans told Parliament on March 8th, 1921, that "the monthly average of admissions for V.D. to hospital was 1·4 per cent. of the total strength" for period Jan. 1st, 1920, to Jan. 31st, 1921.

These statements are not necessarily contradictory, but they are certainly confusing, not to say misleading. If "the percentage of troops suffering from V.D. is 2·6" for 12,000, then 312 men are in V.D. Hospital. (But Dr. Turner says there were 500 plus E.T. cases!) The figure quoted by Sir L. Worthington-Evans—1·4 per cent. per month—is equal to *168* per 1000 per annum. If that is the average number of V.D. cases, how can 2·6 per cent., or 312 men, be correct? Still less correct is Dr. Turner's statement of 500 in hospital.

I called on the Rev. Talbot Hindley, of St. John's Vicarage, Upper Holloway, to get his evidence as to the facts (free from the angry and unwarranted criticism to which this gentleman has been subjected, mainly because of something he did not say), and he tells me that he gave five Gospel lectures in the Venereal Disease Hospital at Cologne; that many of the patients were not appealed to by his Mission; but that he was officially informed that over half the patients in the hospital did attend his lectures on each occasion, and that on each occasion his audience numbered over 200 men; thus there would be at least 400 men in the V.D. Hospital, besides those receiving out-treatment, of which he knew nothing. All the men who attended his lectures were hospital patients in blues. If this statement is correct, Dr. Turner's evidence is corroborated and Sir L. Worthington-Evans's statement is contradicted.

Finally, on page 233 of the National Birth-Rate Commission's Report there is published a letter from the War Office stating that the rate for June quarter, 1920, was *53·79* (contraction rate); for September quarter, 1920, *38·38*. This means that the rate for the June quarter of 1920 was *215* per 1000 per annum, or nearly as high a rate as the Canadians had when they first landed in England.

[1] Journal of the American Medical Association, 1920, lxxiv. p. 1158.

The following paragraph I copy literally from the *Times* of May 22nd, 1920, to show what a false impression truthful figures can make:—

VENEREAL DISEASE IN THE ARMY.

Mr. Churchill, in a written answer to Captain Elliot, states that the approximate ratios per 1000 of admissions for venereal disease in the British Army are as follows:—United Kingdom: 1918, 43; 1919, 59; first quarter, 1920, 14·8. France: 1918, 32; 1919, 67; first *quarter, 1920, 40·5. Army of the Rhine: 1919, 46*; first quarter, *1920*, 42·3. The ratios for 1919 and 1920 are to a large extent fallacious, he adds, owing to rapid demobilisation. The latest information shows some improvement in France and Germany.

Now the rates quoted herein for France for 1918 and 1919 are apparently annual rates, and the rate for 1920 is a quarterly rate, hence comparative rates per 1000 per annum are: 1918, *32;* 1919, *67*, or is it 268? 1920, *40·5* × 4, 162. The Rhine rates are, apparently, per 1000 per annum: 1919, *184*; 1920, *169* (March quarter), and on May 22nd Mr. Churchill says there is "some improvement," the "improvement" being a rise to 215 per 1000 per annum for the June quarter, 1920! Now what are the actual facts?—I am, Sir, yours faithfully,

ETTIE A. ROUT,
Late Hon. Sec., New Zealand Volunteer Sisters.

March 18th, 1921.

DANGEROUS DRUGS ACT, 1920.

To the Editor of THE LANCET.

SIR,—"A Member," writing in your issue of March 19th, suggests that I may be mistaken if my letter, which appeared in your columns of the 12th, intended to imply that "the Council of the London and Counties Medical Protection Society voices the medical opinions of the society's contributors, inasmuch as they are not in any way consulted." It is, of course, impossible to take a referendum of members on every subject that comes before the Council of the society, but members are, I think, quite well aware that the opinion of any individual member, if communicated to the Council, receives careful consideration. The great majority of the members of Council and all the officers are elected annually, and are therefore as representative as is possible of the members of the society. Moreover, at the annual meeting (which this year will fall on April 6th) every member who cares to attend can express his opinion on the policy of the Council.

As regards the proposed Regulations under the Dangerous Drugs Act, 1920, I am not aware that any member of the society differs from the unanimous opinion of the Council, and I note that "A Member" himself does not express any disagreement. Of course, it is very seldom that 6000 members of a society will be in absolute agreement on any particular point, but in this case I am not at present aware of any disagreement whatsoever.

We should be very glad to hear from any members of the society who have formed any opinion on the subject. I am, Sir, yours faithfully,

HUGH WOODS,
General Secretary, The London and Counties Medical Protection Society, Ltd.

Craven-street, Strand, W.C., March 18th, 1921.

ANALYSIS OF THE GASTRIC CONTENTS.

To the Editor of THE LANCET.

SIR,—Mr. J. H. Ryffel's paper on this subject in your issue of March 19th gives an incorrect account of the technique suggested by Dr. W. J. Adie and myself and published in THE LANCET of Feb. 26th. Mr. Ryffel states that "recently Cole and Adie have urged the use of thymol-blue working to an end-point, $=\mathrm{HCl.N} \times 10^{-2 \cdot 6}$, or about N/500."

I had hoped that we had made it quite clear that it is not possible to get correct results from free HCl if one works to a reaction more alkaline than about N/100. He goes on to state that "this indicator would leave a large gap between the total acidity and the free HCl so that it would surely be better to retain dimethyl." I completely fail to see why a large gap is undesirable, since it undoubtedly exists in a great many cases.

I maintain that our technique gives an exact measure of the free HCl and therefore of the actual hydrogen-ion concentration of the gastric contents. Dimethyl gives the whole of the free HCl and an unknown fraction of the combined HCl. If it gave the whole of this combined HCl its use might be defended, but since it gives a figure which nobody can possibly evaluate, it is unfortunate that its use should be advocated by a scientist of Mr. Ryffel's reputation.

I am, Sir, yours faithfully,

Biochemical Laboratory, Cambridge, March 22nd, 1921. SYDNEY W. COLE.

TREATMENT FOR INTERNAL CANCER.

To the Editor of THE LANCET.

SIR,—Since August, 1916, I have been treating with apparent success cases of internal cancer, as diagnosed clinically, as they occurred in general practice. This fact, and the contrasted failure of my treatment of many cases of external cancer with the same remedy suggest to me a new clue in the treatment of cancer. I believe that carcinoma is almost, if not always, associated with some form of rheumatism which yields to a course of alum taken internally. The effect is not observed in the subjects of external cancer associated with a gouty disposition, and I have found that cancer of the rectum, anus, and bladder does not respond to this treatment. The prescription which I recommended is:—

℞	Alum sulphate	gr. ii.
	Mag. carb. levis	gr. v.
	Potass. citrat.	gr. v.
	Tr. opii	♏ iii.
	Aq. chloroformi	ʒ ii.
	Aq. ad	℥ i.

℥ i. t.d.s.

30 drops of liq. bismuthi et ammon. citrat. being added in the case of gastric cancer.

An illustrative case is the following:—

Mr. S., aged 60. On Dec. 29th, 1919, I found him in bed with temperature 101° F. and a hard, irregular lump in the cæcum. He had lost weight and complained of recent "rheumatic pains" *shooting up to the right loin.* There was *no vomiting*, but the abdomen was tympanitic. Tongue clean and pulse 70 and bowels well open. He was put at once on the above alum mixture, with a diet of soda-and-milk, beef-tea, and bread-and-milk. On Dec. 30th calomel gr. i. was given four-hourly for relief of distension.

Jan. 1st: Irregular and hard *lump still there, but less painful and* certainly smaller.

Jan. 4th: Calomel is keeping the bowels open; much mucus in the motions, but no blood. Abdomen flatter. T. 100°.

Jan. 7th: T. 99·8°. Growth hardly palpable.

Jan. 9th: T. 98·6°.

Jan. 20th: Putting on weight rapidly with good appetite. Going to the seaside.

This is one out of six cases of hard irregular growth in the cæcum or colon, with shooting pains up to the right loin, treated by this method. Other cases treated with similar success have been carcinoma of the stomach (7), gall-bladder (1), and prostate gland (1). A case of carcinoma of the ovary responded in an encouraging way. I am placing these suggestions on record in order that other practitioners may test a simple but effective treatment in inoperable or incurable post-operative cases.

I am, Sir, yours faithfully,

REGINALD LARKIN, M.D. Lond., M.R.C.S.

London, S.E., March 18th, 1921.

MATERNITY AND CHILD WELFARE CENTRES AND DAY NURSERIES.—In view of inquiries from local authorities and others interested, the Ministry of Health have issued a revised list, with index, of *maternity and child* welfare centres in England and Wales, including, for the first time, a list of day nurseries. The list contains the names and addresses of 735 centres and 140 day nurseries conducted by voluntary societies and of 1188 centres and 44 day nurseries conducted *by local authorities.* At about 150 of the centres special *dental treatment* is provided, while *others have special arrangements* for eye and ear treatment. While the centres in the first part of the statement are primarily consultation centres for nursing mothers and children under 5, some are fully equipped for ante-natal consultations. There are now separate lists for residential and non-residential institutions. The Ministry advise that consultation centres should be reserved for healthy women and children, and that where possible treatment should be given at special treatment centres which may be established at a hospital or combined with a sc[illegible] clinic, and may take cases from a number of consulta[illegible] centres. The list is obtainable from His Ma[illegible] Stationery Office, or through any bookseller, at 2s. net.

Parliamentary Intelligence.

HOUSE OF LORDS.

WEDNESDAY, MARCH 16TH.

Special Committee on Venereal Diseases.

Lord **WILLOUGHBY DE BROKE** called attention to the Report of the Special Committee on Venereal Diseases, asked the Government what steps were being taken to give effect to its findings, and moved that the Report should be printed and issued as a Parliamentary paper. He said on the last occasion when he raised the question Lord Sandhurst, in response to a request for certain figures with regard to the Portsmouth area and the incidence of venereal disease there as compared with other areas in the United Kingdom, produced a figure which, owing to its magnitude, was positively astounding. He presumed that the noble lord was supplied with the figure by the Ministry of Health. Lord Sandhurst, or at any rate those who supplied him with the figures, knew perfectly well that he (Lord Willoughby de Broke) was asking for figures with regard to the area of which Sir Archdall Reid was the A.D.M.S. in order to prove that under the system of self-disinfection which he had caused to be carried out there was a decrease in venereal disease to a point that was almost negligible. It would almost seem that at the Ministry of Health they were animated by a desire to discredit the figures given by Sir Archdall Reid, because they roped into Lord Sandhurst's answer not only the venereal cases in Sir Archdall Reid's command, but all the other infections in the whole of the district, as well as those which were imported into the district from the outside. Fortunately the whole thing was exposed by Sir Archdall Reid himself, and the fallacy of the figures with which Lord Sandhurst had been supplied was admitted in a White Paper subsequently published by the Government, in which it was shown that the figures given were between three and four times in excess of the actual numbers. He did not charge anybody with a deliberate breach of good faith, but the production of figures of this kind was not calculated to raise public confidence in statements put forward by the Ministry of Health in reference to self-disinfection. The Committee presided over by the Bishop of Birmingham comprised the heads of almost all the various denominations, and also women doctors and physicians and surgeons of the highest merit, and the Government sent their own witnesses to give evidence before it. It was appointed with the consent and approval, if not at the actual instigation, of the Ministry of Health. The Government were therefore bound to take some notice of the Report and to carry its recommendations into effect. The salient features of the Report were, first of all, that the Committee found that sexual continence was compatible with normal health. They concluded with the strongest possible recommendation that in view of the serious situation parents, teachers, ministers of religion, social reformers, and others should combine in a national effort to assert the moral obligation of chastity. With that recommendation the society to which he belonged was in the heartiest accord, and an injunction of that kind was placed at the head of all their leaflets.

The Policy of Self-Disinfection.

With regard to self-disinfection the Committee said:—

> "Having regard to the disastrous effects of venereal disease on individual and national welfare, the Committee think that the time has arrived when the Ministry of Health should, through local health authorities, draw public attention to the grave menace to national health and welfare which exists from this cause, and should make it the personal obligation on every individual who exposes himself or herself to the risk of infection from venereal disease to take adequate steps to become disinfected, and to obtain medical advice and treatment where necessary until cured or rendered free from infection. It would then be the recognised duty of every individual who exposes himself or herself to the risk of syphilis or gonorrhœa to obtain and apply efficiently suitable disinfectant remedies immediately after intercourse, and, in the event of the development of symptoms of disease, to seek medical advice at the earliest opportunity."

The Committee further stated that no obstacle should be placed in the way of people obtaining the right disinfectants from the chemists, and that if necessary the law should be altered to enable them to do so. It was not really necessary to alter the Act of 1917; it was only necessary that the Ministry of Health should put one of its sections into operation, and through the local health authorities take such steps as would enable chemists to sell to people asking for them such things as were duly authorised by the Ministry and those in authority. The Committee very wisely were of opinion that no further reliance could be placed on an increase of the provision for early treatment of the sym- oms. To provide sufficient of them to serve the whole lation was impracticable, and in the present attitude rds public expenditure it was out of the question. At the best it meant delay of disinfection, and he did not see why the ratepayers and taxpayers should pay for keeping houses where the incontinent might go. It was not denied that the rate of venereal infection in this country was a matter of grave public concern; that it was alarming; that it ought to be, and must be, dealt with; and that nothing very much was being done. Those who favoured the policy of self-disinfection did not shut their eyes to all the other means which might be brought forward some day for the purpose of stamping out, if possible, venereal disease. But the particular policy they were concentrating on at the moment had this advantage: it could be carried out immediately by the Ministry of Health. Supposing they promoted a Bill (which a lot of people thought ought to be done) to make it a criminal offence to communicate the disease to somebody else; there was a very large and highly organised body of opinion in this country which was dead against that. It was dead against anything that would savour of State regulation of vice or a return to a state of affairs analogous to that which prevailed under the Contagious Diseases Acts. They would have great difficulty with that. Compulsory notification, so that patients might, if possible be kept under observation for a long enough period to be cured, if ever they could be cured, was a remedy that was full of pitfalls. The society to which he belonged was perfectly prepared to discuss that and all other remedies, but for the moment they had a practical remedy which had proved to be efficient if it was properly tried, and one which was approved by the very important Committee to which he had referred. The official policy was to exhort people not to commit fornication, and then to tell them that if they did they must consult the doctor at once, either before or after the symptoms arose. That policy might be right or wrong in principle, but it had failed in its object. The manner in which the Government were dealing with venereal disease now was a failure; nothing had been done. The Society for the Prevention of Venereal Disease, to which he belonged, did not intend to depart from their policy, because they considered that that policy had been endorsed by the Special Committee. But at the same time he was not going to any conference in the frame of mind of Sir Anthony Absolute. He hoped that an agreement might be found, but everything depended on the attitude of the Government. The Government could either suppress the report or try to ignore it and let the whole thing drift on in the way they were allowing things to drift now in spite of the terrible incidence of venereal disease; or they could take the statesmanlike course and admit frankly that the application of this knowledge had proved to be sufficient where it had been efficiently carried out—they could take it and direct it in a scientific manner. If they did not do that they would be up against a great danger—namely, that the knowledge of self-disinfection was becoming public property. He was very glad to see that several public health authorities had already adopted their policy. There was a meeting held not long ago, at which several medical officers of health in the London district were present, and a resolution was passed unanimously adopting the policy of self-disinfection.

Drawbacks in Application to Civilian Population.

The Bishop of **LONDON** quite agreed with the noble lord in asking the Government to take the Report into consideration, but he pointed out that there was a very great deal said in the Report against self-disinfection. Who should decide when doctors disagreed?—because it was impossible to describe a greater contrast than that between the evidence of Sir Archdall Reid and that of Colonel Harrison, the man who established venereal disease camps in France. In the Committee itself there was a tremendous difference of opinion. Even in the army a system of self-disinfection, except under skilled instruction, was practically valueless. Colonel Harrison, who supported the practice with hope, thinking that it was going to be a great cure, found tremendous disappointment because it did not come up at all to his expectations. If it had failed in the army, how much more would it fail in a civilian population? And when they found that in order to make it effective every boy and girl had to be instructed from early youth in the use of these things he could not wonder that the people who gave evidence and the members of the Commission said that in many ways the remedy would be worse than the disease. Nothing could be more dangerous than the fancied security which this remedy gave. He was looking at the matter from the medical point of view. From the moral point of view he felt that such a system would debauch the conscience of the country. On the other hand, he thought that the Report was a most fair and modest representation of what was said in the evidence, and he should like it to be shouted from the house-tops that the Committee all agreed that chastity was consistent with the best possible health. He did not say that any individual should not have the right to purchase any disinfectant or cure for any disease from any chemist; he thought they were going too far in shackling individual liberty if they prevented any person doing that. With regard to the provision of ablution centres by local authorities, it was a wrong thing that thousands of pounds of the ratepayers' money should be spent to save a man from the consequences of his sin. He was strongly in favour of the doctor being allowed, under privilege, to communicate the fact to some parent whose young or innocent daughter might be about to marry a diseased man, and he was convinced by the evidence of a leading surgeon after the war that they ought to go still further—that they had come to the point when they must have a medical certificate of health before marriage.

Lord SYDENHAM said he regretted that when he asked Lord Willoughby de Broke to come to a round table conference with the National Council he declined. If the conference had taken place they would have been spared the unedifying spectacle of two bodies with the same object, the one constantly attacking the other in the press. He hoped that at this late hour the noble lord would join hands with the National Council in the work they were trying to carry out. There was no reason to expect any material result from self-disinfection if it was tried among the civil population. This was not really a medical question at all. Medical science had told them that certain disinfectants used very carefully in a certain way and at a certain time would probably have the effect of averting infection. Medical science had also told them that soap and water used under the same conditions would probably be equally effective. The questions were whether the civil population could be induced to adopt disinfection on a large scale, whether they would use it properly and at the right time, and what steps should be taken to induce them to do it. That was not medical, and the layman was quite capable of discussing it. He agreed that there was no reason why the nature and effects of disinfection should be kept secret. The National Council took it up in 1916 because there were very many cases of venereal disease among the troops. They advocated disinfection in the camps and barracks, and Sir Thomas Barlow took great trouble in carrying it out. They published a pamphlet explaining the uses of calomel and permanganate, and laying great stress on the importance of cleanliness. His organisation did not wish to keep back from the public any information that might be useful in combating the disease, but it could not go so far as his noble friend's society in proclaiming benefits which must be problematical. The Government would be ill-advised if it issued a statement which might be misunderstood, and which in that case would certainly lead to an increase of infection.

Need of Agreement in the Anti-Venereal Campaign.

Lord GORELL said for the last four or five months he had been endeavouring to see what could be done to bring about an understanding between the two societies. He had hoped that with the issue of the Report there might be found to be in it sufficient to make it common ground between them. That had, however, not been possible. Taking into consideration the Report he drew up eight points of policy, but before those points of policy had been before a general meeting of the National Council on March 22nd and had been confirmed it was hardly possible for him to state them in detail to the House. They might not be accepted, but they had received the full approval of the Minister of Health, and they were unanimously passed by a very representative executive meeting. He had read the Report and the whole of the evidence, and he could not see how any Government could possibly take action upon the lines of the Report, because it was made by a Committee of people who held very different opinions. It was his (Lord Gorell's) duty to give the House not opinions but facts on the other side. He had received a letter from a gentleman who was described by the Bishop of Birmingham—the Chairman of the Committee which produced this Report—as one who had given almost his life to the study of venereal disease. He was a member of the Committee, and was chosen to start the evidence. He had been 25 years a surgeon in the London Lock Hospitals, male and female; he controlled the venereal department of Charing Cross Hospital, and during the war he was in charge of a venereal department. He wrote:—

> "At two venereal disease clinics—Charing Cross Hospital and the London Lock Hospital, the largest clinic in the Empire—during the last four or five months I have been collecting statistics of the number of patients who have used self-disinfection after intercourse. (A) What disinfectant used? (B) How soon after connection? (C) What degree of thoroughness? The figures are at present not enough to be considered conclusive, but as far as they go they bear out what I have always said: self-disinfection will not diminish even the immediate numbers of true venereal disease. Remotely I believe it will produce an increase of venereal disease by giving a sense of false security. Self-disinfectants have prevented, and will continue to prevent, dirt diseases—e.g., septic sores, &c.
>
> About 20 per cent. of the labouring classes had used self-disinfection and it had failed. About 30 per cent. of the educated classes had used self-disinfection and it had failed. I believe that gonorrhœa is infected directly into the canal, especially in Jews; therefore washing outside is useless. In some of the above cases the appearance of the two diseases was postponed for a very long time, that is, the incubation period was greatly increased—a terribly dangerous happening, as during this period others, wives or other women, had been infected by the 'self-disinfectors.' I do not think it would be wise to quote percentages for this matter yet."

He quoted that to show that there was grave doubt at the present time, and need for a great deal more examination and gathering together of statistics before any definite pronouncement could authoritatively be made. At the same time he heartily supported the view that they could not afford to ignore the evidence or to allow matters to drift.

Further Action Imperative.

Viscount KNUTSFORD said he wanted to urge on the Minister of Health that the time for doing nothing had long since passed, and that they must not be afraid because of possible evils which might never happen to take vigorous action. The figures of venereal disease in this country were almost too great to be believed. At the London Hospital alone they had 23,000 new cases last year; that was four times the number they had a few years ago. It was impossible any longer to do nothing; they must do something. He remembered going to a Christmas party at a hospital, and the doctor took him in to see 40 little children, innocent sufferers (their mothers also innocent sufferers), and he said that if it had not been for the work in that hospital the only place in which he (Lord Knutsford) would have been able to see them would have been in the post-mortem room. If he were Minister of Health he would have a very energetic propaganda. He would preach that continence and chastity were consistent with vigour of mind and body. He would paint in the most awful colours the horrors and the suffering caused by these diseases, and would do everything to instil into the public a fear of contracting these diseases. He would tell them the dangers and how to avoid the dangers. He entirely agreed that self-disinfection, unless it was taught properly, was not an efficient safeguard; but they were not doing anything to give the people the knowledge which was a small protection. It was the duty of those who knew to teach others what they should do. He would open more clinics to which people who were diseased could come to be cured. The expense of the clinics would be very great, and the patients who went to them ought to be made to pay.

The Earl of MALMESBURY, as a member of the Joint Committee which considered the Criminal Law Amendment Bill, said he was more impressed by the evidence given by Sir Archdall Reid than by that of Colonel Harrison. But whether Sir Archdall Reid or Colonel Harrison was right it was the duty of Parliament to consider what steps should be taken, and taken soon, to prevent the spread and increase of this disease.

Lord ASKWITH asked if we were to go on with 800,000 cases of venereal disease in the country and increasing every day? It was absurd. No obstruction should be placed in the way of disinfection. That system had been tried in Portsmouth and other centres. It had been endorsed by some of the principal medical officers of health in some of the most crowded districts. They could not say that those men were wrong in adopting this method of disinfection and in saying that it could well be employed. He should support Lord Willoughby de Broke if he went to a division.

The Earl of CLANWILLIAM said he hoped the Government if they could not agree to his noble friend's motion would do something to help the cause.

Government Proposal for a Round-Table Conference.

Viscount PEEL, replying for the Government, said he trusted that Lord Willoughby de Broke would meet with the others around a table in a month or so and that the societies would arrive at a common policy and advise the Ministry of Health. Lord Knutsford knew well that the object of making treatment free was to persuade the largest possible number of people suffering from these diseases to go to the centres in the national interest, but if the noble lord with his experience thought this treatment ought to be paid for that view would have much weight with the Ministry of Health. He would remind their lordships that the Committee, consisting of medical officers of several Government Departments, reported unanimously against the advocacy of self-disinfection for the civilian population, after considering the war experience of the several armies. As regarded the Report of the Special Committee he would point out that medical opinion was very much divided on the question of self-disinfection. It was very important before any consideration was given to public opinion or moral considerations that they should arrive at some definiteness as to what medical opinion was on this question of disinfection. It was generally agreed that the danger of infection became slight and remote if the process of disinfection was carried out by a qualified medical practitioner. It was at the same time felt that it was not practicable to give such instruction to civilians as would ensure that the disinfectants were thoroughly and intelligently applied; further, medical authorities held that the spread of knowledge as to the efficiency of disinfectants if properly applied would lead to persons running the risk of infection who would not otherwise do so, and thus spread the disease. Another danger strongly pointed out by the doctors was that these disinfectants would be used in many cases as a substitute for the treatment of the disease. He was sorry to say that he could not give any very definite information at present on behalf of the Ministry of Health because the question would very shortly receive the attention of the Cabinet. He could only say that speeches on that debate would be very carefully considered. The Report of the Special Committee was not an official Report. If it were published as a Parliamentary Paper it would undoubtedly give colour to the view that this was an official Committee and that to some extent the views expressed were authorised by the Government. He hoped that his noble friend would not press the point.

Lord WILLOUGHBY DE BROKE said he should press the matter to a division.

On a division the motion was defeated by 29 votes to 9.

THURSDAY, MARCH 17TH.

Criminal Law Amendment Bill.

The House received the Report of amendments on the Criminal Law Amendment Bill and they were agreed to.

HOUSE OF COMMONS.

WEDNESDAY, MARCH 16TH.

Venereal Disease.

Viscountess ASTOR asked the Minister of Health whether it was proposed to depart from the policy of dealing with venereal disease which was adopted by him on the unanimous recommendation of the Inter-departmental Committee which reported last spring after taking full evidence.—Dr. ADDISON replied: The question whether any modification is required in the policy adopted in dealing with these diseases is now under consideration, and I am not at present in a position to make a definite statement on the subject.—Major FARQUHARSON: Is the right honourable gentleman aware that the great weight of evidence given before the Inter-departmental Committee and before the Birth-rate Commission was entirely against the idea that packets for self-disinfection were efficacious means of stopping or preventing venereal disease?—Dr. ADDISON: I believe that statement is correct, and I think it is also supported by the experience of the various armies, but the whole matter is under consideration.—Major FARQUHARSON: That point is kept in view at all events.

Royal Naval Hospital at Yokohama.

Commander BELLAIRS asked the First Lord of the Admiralty what was the accommodation in beds for patients of the British Royal Naval Hospital at Yokohama; what was the staff and the maximum and minimum number of patients accommodated in 1920 or latest year available; and whether any expense was incurred in 1920 in sending officers or officials to inspect or overhaul the hospital.—Sir JAMES CRAIG (Parliamentary Secretary to the Admiralty) replied: As regards the first part of the question the particulars are as follows:—Accommodation, 97 patients; staff, 1 surgeon-commander, 4 sick-berth staff, and 13 native employees (hired); maximum number of patients under treatment 1920, 8; minimum number ditto, nil. The answer to the last part is in the negative.

Committee on Medical Records.

Sir WILLIAM DAVISON asked the Minister of Health what was the precise composition of the committee set up to deal with medical record cards.—Dr. ADDISON replied: The committee, under the chairmanship of Sir Humphry Rolleston, was composed in all of 17 persons, 14 being medical men. There are attached to the committee as members three lay administrative officers. Of the 14 medical men on the committee four were in insurance practice at the time, and a fifth had been in such practice until shortly before the committee's appointment.

Medical Officers on China Gunboats.

Commander BELLAIRS asked the First Lord of the Admiralty whether there was a medical staff of a surgeon and a sick-berth attendant to a remaining crew of 12 men in each of our river gunboats in China; whether he was aware that the American and French river gunboats did not carry doctors; and whether the Board would consider the economy which could be made by relying on the missionary doctors along the rivers.—Sir JAMES CRAIG replied: The Upper Yangtse has two gunboats, with one medical officer and one sick-berth rating between them; the Lower Yangtse has eight gunboats, with five medical officers and six sick-h ratings; the West River has *four gunboats*, with two ical officers and two sick-berth ratings. There is no information as to whether the American or French gunboats carry medical officers. It is not considered desirable or, indeed, practicable, to rely on the services of missionary doctors for medical attendance on ships' companies of the gunboats on these rivers. The complements of the vessels vary from 25 to 53, and are not as suggested by the honourable and gallant Member. Owing to the climate and the difficulties as regards obtaining good vegetables sickness has to be provided against, as well as the possibility of casualties in local disturbances.

State Contribution to Health Services.

Mr. TREVELYAN THOMSON asked the Minister of Health whether, in view of the results obtained from the activities of local authorities in the exercise of their powers for the amelioration of the health conditions of their areas, he would see that no curtailment took place in the grants made from the Exchequer in support of school clinics, maternity welfare centres, the care of tuberculosis cases, and similar work, when preparing his estimates for the coming financial year.—Dr. ADDISON replied: My right honourable friend the President of the Board of Education has responsibility in respect of the provision for school clinics. As regarded the other services mentioned the amounts inserted in my estimates for the next financial year are such as are required to provide the State contribution towards existing services and commitments, and also for such extension as can be shown to be necessary for immediate and urgent health requirements.—Dr. NATHAN RAW asked the Minister of Health what grants were made by his department to local authorities towards the cost of the treatment of tuberculosis, and what proportion of the total expenditure was represented by those grants.—Dr. ADDISON replied: Grants approximating to £970,000 will be made during the current financial year towards the expenditure of local authorities on the treatment of tuberculosis. The grants represent less than ½d. in the £ on the total sums voted by Parliament for the supply services of the country. In addition to these maintenance grants, grants in aid of capital expenditure amounting approximately to £360,000 will also be made.

Report on Official Statistics.

Mr. WILSON-FOX asked the Lord Privy Seal if he would state when the recommendations of Sir Alfred Watson's Committee on Official Statistics would be published.—Mr. LLOYD GEORGE, Prime Minister, replied: The recommendations of Sir Alfred Watson's Committee on Official Statistics will be published as a Stationery Office publication at an early date.

Public Health (Tuberculosis) Bill.

Dr. ADDISON introduced the Public Health (Tuberculosis) Bill "to make further provision with respect to arrangements by local authorities for the treatment of tuberculosis." The Bill was read a first time.

THURSDAY, MARCH 17TH.

Non-attributable Disability.

Sir THOMAS BRAMSDON asked the Minister of Pensions whether, seeing that a pre-war invalid with ten years' service who served upwards of four years during the war and was invalided with a non-attributable disability received nothing for his war service, whereas a new entrant serving a similar period during the war and invalided with a disability attributed to his own carelessness or neglect could receive an allowance up to a maximum of £150, steps would be taken to remedy this injustice.—Mr. IAN MACPHERSON replied: Men invalided and pensioned before the war who were called up for service were entitled to receive payment of their pensions while serving and to count their further service for increase of pension. Allowances under Article 7 of the Royal Warrant and Order in Council were not intended for men of this class, but for men who had no specific claim to compensation. The allowances are purely temporary and only in very exceptional circumstances would the maximum, or an amount approximating thereto, be granted, and the receipt of a temporary allowance cannot generally compare favourably with the grant of a life pension or increased life pension. If in any very exceptional case it were clear that a temporary allowance under Article 7 would be more to the man's advantage than a life pension, this allowance would be paid to him instead of pension.

Treatment of Neurasthenic Ex-Service Men.

Sir WALTER DE FRECE asked the Minister of Pensions whether his arrangements were now complete for the treatment of ex-Service neurasthenic patients; and how many such men he had hitherto treated.—Mr. IAN MACPHERSON replied: The facilities for the treatment of ex-Service neurasthenic patients have already been greatly extended, and the arrangements made by the Ministry are still in process of development. It would need a prolonged investigation to ascertain the total number of men treated since the formation of the Ministry. The number of officers and men at present under treatment is 9921.

Medical Record Cards.

Mr. ALFRED T. DAVIES asked the Minister of Health whether large numbers of patients' records cards had been inaccurately filled up by medical men or others; whether the numbers had increased during the past three months; whether he was satisfied with the present method of inspection; and to what he attributed the growth of inaccuracy in these returns.—Dr. ADDISON replied: In the filling up of 13,000,000 cards a certain number of inaccuracies are inevitable, but my information is that the tendency is all in the direction of improvement, and the last part of the question does not, therefore, arise. The answer to the third part is in the affirmative.

Advisory Committee on Blind Welfare.

Mr. MYERS asked the Minister of Health whether the term of service of the members of the advisory committee on the blind expired in December last; whether any committee was now in existence; and, if so, would he state its composition.—Dr. ADDISON replied: The answer to the first part of the question is in the affirmative. I am proposing to set up a new advisory committee, and hope to be in a position to announce its composition very shortly.

Financial Position of the Hospitals.

Sir GODFREY COLLINS asked the Minister of Health when the Report of the Committee on Hospital Finances, presided over by Lord Cave, would be published; could he inform the House as to the recommendations of the committee; and what steps he proposed to take in the matter.—Colonel MILDMAY asked the Minister of Health whether the Report of Lord Cave's Committee at present considering the financial position of hospitals was likely to be published soon; and whether, failing the possibility of such early publication, any interim report would be forthcoming, in view of the urgency of the issues under discussion, and of the fact that the future policy in this connexion of the Approved Societies and of other bodies concerned would shortly be considered and shaped.—Dr. ADDISON replied: An interim report is being issued to-day on the question of contributions to hospitals out of the valuation surpluses of Approved Societies. I am informed that the hearing of evidence will be completed by the beginning of May and the Committee hope to present their Final Report before the end of that month.

MONDAY, MARCH 21ST.

Alcoholic Liquors as Medicine.

Sir J. D. REES asked the Prime Minister whether, in view of the fact that beer as well as whisky had been allowed to be a medicine in prohibitionist America, he would arrange to relax the restrictions imposed upon the people of the United Kingdom under the Defence of the Realm Act and Central Control Board (Liquor Traffic).—Mr. LLOYD GEORGE replied: The Government propose to deal with this subject at an early opportunity.

Invaliding Disabilities of Post-war Invalids.

Sir THOMAS BRAMSDON asked the Secretary to the Admiralty whether the invaliding disabilities of post-war invalids would be viewed in the same light as that now obtaining for men invalided during the Great War; and whether the scales recently introduced would be applicable to post-war cases.—Sir JAMES CRAIG replied: Apart from disabilities aggravated by, but not due to, naval service, in connexion with which certain recommendations made by a Medical Committee set up by the Minister of Pensions are now under consideration, the answer to the first part of the question is generally in the affirmative. As regards the second part, a special scale has been approved for post-war cases, based on the principle that the exceptional circumstances inseparable from service under conscription will not be present in the case of a professional service.

Sir THOMAS BRAMSDON asked the Secretary to the Admiralty whether a Pensions Appeal Tribunal, similar to that set up for men invalided during the war, could be constituted to deal with pre-war and post-war disability pensioners.—Sir JAMES CRAIG replied: It is not considered that any necessity arises for a Pensions Appeal Tribunal in the case of the permanent service, having regard to the stringent medical examination applied to all new entries. In any event it would be impracticable to reopen the cases of pre-war disability pensioners.

Pension Appeals in London.

Lieutenant-Colonel Sir FREDERICK HALL asked the Minister of Pensions how many appeal tribunal courts had been set up in the London region; how many appeal cases there were still waiting for the tribunals to deal with; what was the approximate number of cases that were heard by the various tribunals in the London region each week; and what steps were to be taken in order that appellants' cases might in future be decided without their having to wait such a long period for their appeals to be heard as they had in the past.—Sir G. HEWART (Attorney-General) replied: I understand that pension appeal tribunals are distributed in various large centres in England and Wales (including London) in accordance with the number of cases to be dealt with in such centres, which varies from month to month. Since Feb. 28th six tribunals have been sitting in London. Approximately 300 appellants per week have been afforded an opportunity of having their cases dealt with during that period. There are at present 3000 cases awaiting hearing in London, of which 1565 have been received by the Pension Appeal Tribunals during the last month. Up to the present time the average period elapsing between the date on which an appeal was received by the tribunal and the date on which it was listed for hearing has been, I am told, six weeks. Steps to provide for the setting up of additional tribunals are under consideration.

Treatment of Bilharziasis.

Captain THORPE asked the Minister of Pensions whether, in view of the successful treatment by antimony of ex-Service men who contracted bilharziasis during the late war, he could hold out any hope of similar treatment at public expense to pensioners who contracted the disease in the South African campaign and were still suffering.—Mr. IAN MACPHERSON replied: This matter is at present under consideration.

TUESDAY, MARCH 22ND.

Washington Maternity Convention.

On the second reading of the Consolidated Fund Bill Mr. CLYNES and other Members raised the question of Article 3 of the Washington Convention dealing with maternity benefits, and asked the reason why the Government had decided not to ratify the Article and had not brought it before Parliament in the form of legislation.—Dr. ADDISON (Minister of Health) said that the initiation of legislation in this country rested with Parliament, and had the Government ratified the Washington Convention in regard to maternity the position would have been that an outside body would be able to compel the Government to submit legislative proposals to that House against its desires. To that the House would never submit. They had already in this country a system which was double-barrelled for providing maternity benefits—namely, the Insurance Act and the system administered by the local authorities. These recommendations cut right across the system in this country which was acting with singular success. The Washington Convention related only to employed women, which would mean that in this country about 460,000 women would be eligible, while 3,540,000 women, the wives of insured persons, would be excluded. To carry out these recommendations with regard to all these women would cost an additional £15,000,000. The system of maternity and child-welfare cost 1*d.* in the £ on the rates, rather less than £900,000 being contributed out of the Exchequer. The results had been brilliant. The rate of infantile mortality in London had dropped from 106 per 1000 in 1913 to 75 per 1000 in 1920. There had, of course, been contributory causes. People had been better nourished and the national conscience had been more fully awakened since the war.

BOOKS, ETC., RECEIVED.

Medical News.

UNIVERSITY OF OXFORD: *Radcliffe Travelling Fellowship.*—The Master and Fellows of University College announce that the Radcliffe Trustees have elected Tom Sydney Nelson, M.A., B.M., University College, to a Radcliffe Travelling Fellowship of £200 for three years.

Radcliffe Prize, 1921.—The Master and Fellows of University College have awarded a Radcliffe Prize of £50 to Edward Palmer Poulton, M.A., D.M., F.R.C.P., Balliol College, for his researches in physiology and pathology.

UNIVERSITY OF MANCHESTER.—At examinations held recently the following candidates were successful:—

THIRD M.B., CH.B. EXAMINATION.

General Pathology and Morbid Anatomy.—Elsie C. Begg, Lionel Boyars, F. W. W. Fox, E. S. Frischmann, Richard Handley, Mary Kent, C. B. Kirkbride, G. A. Lord, Greta Lowe, G. L. Meachim, A. A. Pomfret, Eleanor P. Smith, J. H. Struthers, and C. B. V. Walker.

DIPLOMA IN PUBLIC HEALTH.

Marion Draper and J. H. Sheldon.

UNIVERSITY OF DURHAM: FACULTY OF MEDICINE.—At examinations recently held the following candidates were successful:—

THIRD EXAMINATION FOR DEGREES OF M.B., B.CH.

Materia Medica, Pharmacology and Pharmacy, Public Health, Medical Jurisprudence, Pathology and Elementary Bacteriology.—John N. Alexander, Florence Bentham, Robert W. Locke, George C. E. Reffell, Charles A. Wilson, Eleanor Hilda Wylam, and Ella Lees Young.

THIRD EXAMINATION FOR LICENCE IN DENTAL SURGERY.

Anatomy, Physiology, and Histology, Dental Anatomy, Dental Histology, and Dental Materia Medica.—William A. Cowden, Selby Hutson, Eric W. Manners (honours, second class), Robert H. Reay (honours, second class), John N. Slack, James W. Vasey, and Gladwyn Williams.

QUEEN'S UNIVERSITY OF BELFAST.—At the graduation ceremony held on March 19th the following degrees were conferred:—

M.D.—James Donnelly and Frederick Hopkins.

M.B., B.Ch., B.A.O.—With honours: First class: John A. Smyth. Second class: Eileen O. Bartley and Samuel A. Thompson.

Pass: John Black, Sloan M. Bolton, John W. Bradbury, Henrietta Bradshaw, Patrick P. Connolly, Maurice Emery, James English, James Gaussen, Edward M. Hadden, Henry Harris, Stanley M. Kirk, David Loughridge, Robert J. McMullan, Beattie McNeill, Alexander McSparran, Edward C. Patterson, John Patton, John D. Reynolds, William J. Simpson, Arthur C. Sinclair, Kathleen R. Snodgrass, and John Young.

Diploma in Public Health.—Joseph M. Clearkin, John H. Davison, James W. Kernohan, Olga R. I. Love, John A. Martin, Grahame Patton, William Saunderson, Robert L. Sinclair, and Samuel J. Stewart.

SOCIETY FOR THE STUDY OF INEBRIETY.—The annual meeting of the society will he held at the Medical Society of London, 11, Chandos-street, London, W., on Tuesday, April 12th, at 4 P.M., when Dr. H. H. Dale, F.R.S., will open a discussion on the Use of Alcohol in Medicine.

PANEL NURSES.—At a recent meeting at the offices of the Leicester Insurance Committee of representatives of Approved Societies a scheme of nursing for the city of Leicester was discussed. Twenty societies, including friendly and industrial societies and trade unions, were represented. The subjects considered included the advisability of using the accumulated funds of the Approved Societies to add nursing to the benefits already enjoyed by the insured, and the possibility of using the District Nursing Association in this connexion. It was suggested that under the care of trained nurses patients would often recover more quickly and that the funds of the Approved Societies would in the long run benefit. The following resolution was passed:—

> "That this meeting of representatives of Approved Societies heartily supports the idea of a scheme of nursing for the city of Leicester, and agrees that a representative committee be appointed to formulate such a scheme and report to a future meeting of representatives of societies."

Discussion also arose at a meeting of the Preston Insurance Committee on the question of provision for the nursing of insured patients. In this case a nursing centre was proposed, to provide which the societies might be asked to pay 3*d.* per member per year. Fifteen nurses was the number suggested. One member of the Committee, in welcoming the scheme, rejoiced to hear that the intention was to appoint nurses who would nurse and not simply nurses who went about inspecting. It was decided, after discussion, to circularise the Approved Societies in the borough having over 100 members to ascertain whether they were in sympathy with a scheme for nursing insured persons and would be prepared to contribute a few pence (say 3*d.*) per member per year in case such an organisation was formed Preston.

CONGRÈS INTERNATIONAL DE MÉDECINE ET DE PHARMACIE MILITAIRES.—This congress, organised by the Service de Santé de l'Armée Belge, will be held at Brussels from July 15th to the 20th, under the presidency of Dr. Wibin, Inspecteur-Général du Service de Santé de l'Armée. The subjects to be discussed include the general organisation of the health services of armies and their proper relation to the Red Cross, the clinical and therapeutic study of poisonous gases used in warfare, the struggle against tuberculosis and venereal diseases in armies, the treatment of fractured limbs, and the purification of drinking water. Communications on any of these subjects should be written in French, English, or Italian, and should be sent before May 1st to the Secretariat Général du Congrès, Hôpital Militaire de Liège (Belgique). The fee for the congress is 25 Belgian francs.

LIVERPOOL DISPENSARIES.—The annual meeting of subscribers to the Liverpool Dispensaries was held at the Town Hall last week. Mr. S. Mason Hutchinson, the President, stated that for some years the dispensaries had been making a charge for treatment. Originally it was 1*d.*, now it was 3*d.* Most of the patients were able to pay this higher charge, and paid it willingly. The committee did not encourage those patients to come to the dispensaries who could pay for private medical attendance. The total number of patients in 1920 was 26,590, against 25,253 in 1919 and 29,964 in 1918. The medical officer of health had acknowledged the important part played by the dispensaries in the early recognition of infectious diseases—531 cases having been notified during the year. Attached to the North Dispensary there was now a school and infant clinic which was doing very valuable work. The treasurer's report showed a deficit on the year's working of £248, and at the end of the year there was a bank overdraft of £1874. The Lord Mayor moved the adoption of the reports, and stated that the fact that the patients paid what they did was an indication that they recognised the beneficent character of the work carried on by the dispensaries. Dr. A. A. Mussen, assistant M.O.H., stated that the Infant Welfare Centre had been attended during the year by close on 3000 people. The work was preventive, and he was sure that the education given to the mothers did much to reduce the infant mortality in the district. At the children's clinic during the past four years over 4000 cases of operation for tonsils and adenoids had been dealt with without mishap.

ROYAL MEDICAL BENEVOLENT FUND.—At the meeting of the committee held on March 8th 17 cases were considered, and £175 voted to 14 applicants. The following is a summary of some of the cases relieved:—

Widow, aged 60, of M.R.C.S., who practised in Essex and died in February, 1921. Applicant's husband had been unable to practise for some time owing to failing eyesight and old age, and the small amount of £60 left at his death from the practice was much reduced by funeral expenses and debts. The widow's sole income is £37 10*s.* interest on her own money invested in War Bonds, and at present her rent and rates amount to £32 per annum. Voted £18 in 12 instalments.—Daughter, aged 49, of M.R.C.S., surgeon at a London hospital and died in 1873. Applicant was operated on in June, 1920, and since has been living on her small savings and cannot possibly return to nursing, her profession, for some considerable time. She asks for temporary assistance whilst incapacitated. Voted £10 in 2 instalments.—Widow, aged 57, of M.R.C.S. who practised at Great Yarmouth and died in 1920. Owing to her husband's indifferent health and a number of bad debts applicant found herself very badly off and has been trying to support herself by temporary employment, and with the help of friends has managed to pay her way, but now asks the Fund to help her as her health has broken down. Voted £18 in 12 instalments.—Widow, aged 44, of L.R.C.P. & S. who practised in Yorkshire and died in 1918. Applicant was left with two children totally unprovided for and asks assistance towards the education of the children. Applicant's father-in-law makes her an allowance, but this help may cease at any time; she augments this by letting apartments. Help has been given by the Irish Medical Benevolent Fund and the Professional Classes War Relief Council. Her rent is £48 per annum. Voted £2 and referred to R.M.B.F. Guild for education grant.—Daughter, aged 70, of M.R.C.S. who held a commission in the R.A.M.C. and was a resident medical officer in London later. Owing to loss of income applicant finds it hard to maintain herself and help an invalid brother on a very limited income, derived from an allowance from the War Office, of £32 per annum, and an allowance from a sister of £20. She has rooms free on condition that her income is not less than £40 per annum. As she is too old to work she appeals to the Fund to help her. Voted £10.—Daughter, aged 65, of M.D. Lond. who practised at Notting Hill and died in 1885 Applicant has supported herself by needlework, but owing to advancing years and failing eyesight cannot do the amount of work necessary to pay her way. The amount she now earns is about 18*s.* per week and her rent is 4*s.* per week. The Fund rendered assistance to the applicant's sister some time ago, but she is now in the infirmary. Voted £12 in 12 instalments.—Daughter, aged 50, of M.R.C.S. who practised at Wigan and died in 1870. Three sisters live together in one room, one an invalid. Applicant made about £50 this year at nursing, but owing to ill-health has applied to the Fund for assistance. The rent of the room is 16*s.* per week. Voted £18 in 12 instalments.

Subscriptions may be sent to the Honorary treasurer, Sir Charters J. Symonds, K.B.E., at 11, Chandos-street, Cavendish-square, London, W.1.

RED CROSS ENTENTE.—In a letter to the *Journal de Genève* of March 17th, Sir David Henderson, director-general of the League of Red Cross Societies, states that a satisfactory understanding has now been reached between the League and the International Red Cross Committee. This arrangement, which only awaits formal sanction, will result in useful collaboration, and place the Red Cross symbol out of reach of petty rivalry.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An extraordinary comitia was held on March 21st, Sir Norman Moore, the President, being in the chair. The President delivered the annual address and read eloquent obituary notices of the seven Fellows deceased during the past year—viz., Dr. M. Handfield-Jones, Dr. Philip John Hensley, Dr. David Lloyd Roberts, Dr. William Murray, Sir Frederick Taylor, Dr. William Odling, and Sir Felix Semon. Sir Norman Moore was then re-elected President. Licence to practice was granted to Evelyn Francis Bebbington, of Liverpool University.

PRESENTATION TO A MEDICAL MAN.—Dr. Alexander Stookes, senior surgeon to the Samaritan Hospital for Women, Liverpool, and one of the physicians to the Maternity Hospital, Liverpool, was entertained to dinner at the University Club on March 19th by his colleagues and friends on the occasion of his retirement. Professor Henry Briggs presided, and was supported by Mr. Rankine (chairman of the Maternity Hospital), Miss F. Ivens, M.S., Dr. T. R. Bradshaw, Professor L. R. Wilberforce, Dr. Blair Bell, and Mr. T. H. Bickerton. The company included the matrons of the Maternity and the Samaritan Hospitals. The toast of the "Guest of the Evening" was proposed by Mr. Rankine and supported by Dr. Bradshaw. Professor Briggs then presented Dr. Stookes with a substantial cheque. Dr. Stookes delivered a speech full of pleasant reminiscences of Liverpool 30 and 40 years ago, and thanked his friends in cordial terms for the honour they had done him. In the course of the evening speeches, paying tribute to Dr. Stookes as a surgeon and a man of many interests, were delivered by Miss Ivens, Professor Wilberforce, Mr. Bickerton, Dr. Blair Bell, and Dr. Glynn Whittle.

THE POSITION OF POOR-LAW MEDICAL OFFICERS. In the impasse that exists in the greater part of Ireland between local authorities and the Local Government Board the officers of the local authorities find themselves in a peculiarly difficult position. In most cases these officers are appointed by the local authority, subject to the approval of the Local Government, are paid by the local authority, and cannot be dismissed without the authority of the Local Government Board, which itself has the power of dismissal under sealed order. In the case of medical officers a small fraction of their salaries was contributed from central funds, but where the local boards have repudiated the authority of the Local Government Board these contributions are not paid and the entire burden of the salaries falls on the ratepayers. A medical officer, therefore, finds himself in the curious position of being paid by one body while holding his office at the pleasure of another. To add to his difficulty, these bodies issue contradictory orders and each expects his obedience. A Poor-law medical officer is bound to make certain returns to the Local Government Board. Certain local boards have forbidden their officers to make any such returns. The Local Government Board has retorted by threatening those who do not make returns with dismissal. A medical officer in such circumstances must either obey the Local Government Board and forfeit his salary or obey the guardians and be dismissed from his office.

NATIONAL LEAGUE FOR HEALTH, MATERNITY AND CHILD WELFARE.—An English-speaking Conference on Infant Welfare will be held at the Kingsway Hall, Kingsway, London, W.C., on July 5th, 6th, and 7th, Lord Astor in the chair, under the patronage of the Minister of Health. The main subjects to be discussed are (1) residential provision for mothers and babies; (2) inheritance and environment as factors in racial health; (3) the supply of milk, its physiological and economic aspects. Papers will be submitted by a number of authorities from all parts of the world, whose names will be announced in the detailed programme which will shortly be available. Throughout the Conference a mothercraft exhibition will be open from 11 A.M. to 9 P.M., at which the main features will consist of practical demonstrations in important matters relating to infant care. For the benefit of infant welfare workers of all kinds lectures will be given every evening during the Conference on (1) the Ideal Maternity and Child Welfare Centre; (2) Common Infections in Mother and Child; (3) the Tuberculous Mother and her Infant; (4) the Syphilitic Mother and her Infant; (5) the Accessory Factors in Infant Feeding; (6) the Psychology of the Mother and her Child. The Conference fee, including admission to the exhibition and to the evening lectures, the right to receive proofs of the papers to be read, and a copy of the report of the proceedings when published, has been fixed at £1 1s. per member, and tickets for various parts of the Conference can be had at various prices. Further particulars and tickets can be obtained from Miss Halford, 4 and 5, Tavistock-square, London, W.C.1.

ROYAL PORTSMOUTH HOSPITAL.—The annual meeting of this hospital was held at the Town Hall, Portsmouth, on March 22nd. The report stated that 13,596 patients had been treated during the year, compared with 12,062 in 1919. The average cost per bed occupied was £119 5s. 9d., against £115 2s. 4d. in 1919. The ordinary income last year amounted to £15,178—a record amount—against £10,531 in 1919. The annual subscriptions showed an increase of £1204 (£3818 against £2614), and the employees and box collections the splendid increase of £4204 (£4562 as against £358). The mayor has raised towards the deficit on maintenance account the sum of £3150. Legacies amounted to £485. The venereal diseases department had a successful year's working. 1004 new patients attended, and the total number of attendances was 23,674, an increase of 3827 over the figure for 1919. More accommodation being needed, the Portsmouth Corporation has constructed a temporary building for male patients. There are now six beds for female patients and five for male patients. A gratifying feature has been the increase in the number of patients who have come in the early stages of their disease.

Obituary.

WILLIAM IRONSIDE BRUCE, M.D. ABERD.,

PHYSICIAN TO THE X RAY AND ELECTRICAL DEPARTMENTS, CHARING CROSS HOSPITAL.

Dr. William Ironside Bruce died at his residence in London on Monday, March 21st, after a severe and distressing illness of about two months' duration. His early death has cut short a career of good service and much usefulness, and his loss will be greatly felt by many members of the medical profession, and is especially lamented by Charing Cross Hospital and its medical school.

William Ironside Bruce was the second son of the late Dr. William Bruce, of Dingwall, and a nephew of Dr. J. Mitchell Bruce. He was born at Dingwall and was educated at the University of Aberdeen, where he obtained the degrees of M.B. and Ch.B. in 1900, and then took service as civil surgeon in the South African Field Force. While in South Africa he took much interest in the early application of X rays for the diagnosis of war injuries, and when it became necessary to appoint an assistant to the late Sir J. Mackenzie Davidson at Charing Cross Hospital he was selected for this post. He remained in the service of Charing Cross Hospital to the time of his death and became responsible for an exceedingly efficient X ray department.

Ironside Bruce was intensely interested in the scientific developments of his subject, and especially in its practical application to the diagnosis and treatment of disease. The whole of his later work was built on a good foundation, as is evidenced by the publication in the early part of his career of his "System of Radiography with Atlas of the Normal." He was a good teacher—many now engaged in the practice of radiography owe much to his instruction—and was always prompt in service to his professional brethren. With a very complete knowledge of his subject he had a sound and increasing acquaintance with general medicine and surgery. In process of time he became President of the Section of Radiology in the Royal Society of Medicine, and took much interest in the establishment of the special diploma in this subject, now given by the University of Cambridge.

For some months the condition of his health had given anxiety, and at the beginning of the year he was persuaded to take a prolonged holiday. Shortly it was found that his illness was serious, when blood examination established the diagnosis of the severest type of aplastic anæmia and from this he died. Evidence now accumulating, that this condition can be caused by the effects produced on the blood-forming structures of the body by the more penetrating radiations both from X ray tubes and from radium, renders it almost certain that he succumbed as the result of his continuous and enthusiastic work in the subject of his choice.

Appointments.

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.*

BROWNLIE, W. B., M.D. Glasg., has been appointed one of the Medical Referees under the Workmen's Compensation Act for County Court Circuit No. 4.

MCDOWELL, R. J. S., M.B., Ch.B., to be Lecturer in Experimental Physiology and Experimental Pharmacology at the University of Leeds.

PINHEY, E. T., M.B., Ch.M. Sydney, Medical Officer of the City of London Union.

WHITEHEAD, H., M.D. Manch., D.P.H., Medical Officer of Health for Wigan.

University College Hospital: KANE, M. H. K., and BLAKE, J. C., M.R.C.S., L.R.C.P. Lond., House Physicians; BUTCHER, T. A., M.R.C.S., L.R.C.P. Lond., House Surgeon; KIRTON, C. A., Obstetric Assistant; EADES, R. O., Casualty Surgical Officer; SCANTLEBURY, G. C., Assistant in Ear, Nose, and Throat Department.

Vacancies.

For further information refer to the advertisement columns.

Birmingham General Hospital.—Asst. Visit. Anæsth. £50. Res. Anæsth., H.S., £100 each. H.S. to Skin and Venereal Depts. £125. Cas. H.S. £100.

Birmingham, Rubery Hill and Hollymoor Mental Hospital.—Jun. Asst. M.O. £400.

Brighton, Royal Alexandra Hospital for Sick Children, 10, Dyke-road.—Hon. P. and Hon. Asst. S.

Bristol General Hospital.—H.S. £175.

Central London Ophthalmic Hospital, Judd-street, W.C.—Path. £75.

Charing Cross Hospital, Agar-street, W.C.—Surg. Registrar. £150.

Denbigh Mental Hospital.—Jun. Asst. M.O.—£400.

Dewsbury County Borough.—Asst. Sch. M.O. and Asst. M.O.H. £500.

Dumfries, Crichton Royal Mental Hospital.—Clin. Path. £400.

Ealing Borough.—Asst. M.O.H. £500.

Eastbourne, Princess Alice Hospital.—H.S. £175.

Gloucester County Asylum.—Jun. Asst. M.O. £300.

Greenwich, "Dreadnought" Hospital.—H.S. £150.

Guildford, Royal Surrey County Hospital.—H.S. £150.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—Res. Asst. M.O. £200. Also H.P. £50.

Hospital for Sick Children, Great Ormond-street, London, W.C.—Asst. Cas. M.O., H.S., and H.P. £50 each.

Huddersfield Royal Infirmary.—Two Jun. H.S.'s. £150.

Lincoln County Hospital.—Jun. H.S.—£150.

London Lock Hospital, 91, Dean-street, W.—Pathologist. £500.

Maidstone, Kent County Ophthalmic Hospital for Diseases of the Eye, Ear, Nose, and Throat.—H.S. £300.

Manchester, Ancoats Hospital, Mill-street.—Med. Registrar and Surg. Registrar. £100 each. Res. Surg. O. £250. Res. H.P. £200. Anæsth. 10*s.* 6*d.* per attendance. Also Female M.O.

Manchester Children's Hospital, Gartside-street.—Asst. M.O. £200.

Manchester County Asylum, Prestwich.—Asst. M.O. £572 18*s.*

Manchester, Crumpsall Institution and Infirmary, Crescent-road.—Res. Asst. M.O. £300.

Manchester Royal Infirmary and Dispensary.—Two Hon. Asst. P.'s.

National Hospital for the Paralysed and Epileptic, Queen-square, W.C.—H.P. £150. Asst. P.

Newcastle-upon-Tyne, City Mental Hospital, Gosforth.—Jun. Asst. M.O. £400.

Norfolk Education Committee.—Asst. Sch. M.O. £500.

Northampton General Hospital.—H.S. £200.

North Riding of Yorkshire County Council.—Tuberc. O. £700.

Nottingham, Bagthorpe Institution and Infirmary.—Res. Asst. M.O. £300.

Nottingham City Asylum.—Sec. Asst. M.O. £400.

Oldham Royal Infirmary.—H.S. £200.

Paddington Green Children's Hospital, London, W.—H.P. £150. H.S. £150.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Cas. H.S., Asst. Cas. O., and H.P.'s. £100.

Reading, Royal Berkshire Hospital.—Second H.S. £200.

Rochester, Kent, St. Bartholomew's Hospital.—Jun. Res. M.O. £200.

Rotherham Hospital.—Jun. H.S. £150.

Royal Eye Hospital, St. George's-circus, Southwark, S.E.—Sen. and Jun. H.S.'s. £100 and £70. Also Clin. Assts.

Ryde, Royal Isle of Wight County Hospital.—Vacancy on Hon. Med. Staff.

Salford Royal Hospital.—H.S.'s, and Cas. H.S. £150.

Sheffield, East End Branch of the Children's Hospital.—H.S. £150.

Sheffield Royal Hospital.—H.S. and Asst. Cas. O. £150.

Sheffield Royal Infirmary.—H.S. £150.

Southampton Free Eye Hospital.—Asst. Hon. Ophth. Surg.

Swansea County Borough.—Asst. M.O. £500.

Tiverton Hospital.—H.S. £100.

Wakefield, Clayton Hospital.—Sen. H.S. and Jun. H.S. £250 and £200.

Wandsworth Union, St. James' Infirmary, Ousely-road, Balham, S.W.—Two Jun. Asst. M.O.'s. £300.

Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.

Wolverhampton and Staffordshire General Hospital.—Hon. Spec. for Ear, Nose, and Throat Dept. Also Res. Cas. S. £300.

Worcester County and City Mental Hospital, Powick.—Sen. Asst. M.O. £450.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of a vacancy for a Certifying Surgeon under the Factory and Workshop Acts at Canterbury.

Births, Marriages, and Deaths.

BIRTHS.

DONNELL.—On March 20th, at Hinckley, Leicestershire, the wife of J. H. Donnell, M.B., B.C. Cantab., of a daughter.

HAMILL.—On March 21st, at Weymouth-street, W., the wife of P. Hamill, M.D., D.Sc., F.R.C.P., of a daughter.

MANSON-BAHR.—On March 17th, at Weymouth-street, W., the wife of Dr. Manson-Bahr of a daughter.

PARIS.—On March 14th, at Wimbledon, the wife of Major R. C. Paris, R.A.M.C., of a daughter.

RUDKIN.—On March 15th, at Devonshire-street, the wife of G. W. R. Rudkin, M.C., M.R.C.S., L.R.C.P., of a daughter.

MARRIAGES.

ANDERSON—HOOD.—On March 18th, at St. Columba's (Church of Scotland), Pont-street, S.W., the marriage of Major H. Graeme Anderson, M.D., F.R.C.S., R.A.F., of 75, Harley-street, W., to Gladys, elder daughter of Charles Hood, of Hatch End, Middlesex.

DAWSON—PARKINS.—On March 17th, at St. Clement's Church, Ilford, Ernest Archibald Dawson, L.D.S. R.C.S. Eng., to Dorothy Florence, only daughter of Mr. and Mrs. G. Parkins, of Holcombe-road, Ilford.

FORDYCE—WADDELL.—On March 15th, at the Scottish National Church, Crown-court, London, Captain A. Russell Fordyce, R.A.M.C., to Mary, younger daughter of the late James Waddell, Solicitor, Earlsferry, and Mrs. Waddell, Earlslea, Earlsferry.

LEEMAN—MACGREGOR.—On March 16th, at South Kensington Presbyterian Church, Percival Garmany Leeman, M.C., M.D., to Clara Grace Ellen, only daughter of Mr. Robert MacGregor, London, formerly of South Africa.

DEATHS.

CUMMING.—On March 14th, at the 3rd British General Hospital, Basra, Captain Robert Scott Cumming, M.C., R.A.M.C., aged 27.

DE BRENT.—On March 16th, Mortimer John De Brent, M.R.C.S., Victoria-road, Clapham Common.

KAY.—On March 11th (suddenly), at The Grove, Starbeck, Harrogate, Elizabeth Mary, wife of Walter Smith Kay, M.D., formerly Medical Superintendent of West Riding Asylum, Wadsley, Sheffield.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Friday, April 1st.

SECTION OF LARYNGOLOGY: at 4.45 P.M. (Cases at 4 P.M.)
Epidiascope Demonstration:
Mr. Archer Ryland will give an Epidiascope Demonstration of a Pharyngeal Pouch, dated 1760 A.D.
Cases and Specimens will be shown by—
Mr. G. W. Dawson, Mr. C. W. M. Hope, and others.

SECTION OF ANÆSTHETICS: at 8.30 P.M.
Paper:
Dr. R. L. Mackenzie Wallis and Dr. C. Langton Hewer: A New General Anæsthetic—its Theory and Practice.

Monday, April 4th.

SECTION OF TROPICAL DISEASES AND PARASITOLOGY: at 8.30 P.M.
Papers:
Dr. W. Broughton-Alcock: Laboratory Observations on Pensioners who contracted Malaria in the late War.
Dr. H. C. Lucey: Observations bearing on the Reliability of the Large Mononuclear Leucocyte Count as an Aid to the Diagnosis of Malaria.

Tuesday, April 5th.

SECTION OF SURGERY: SUBSECTION OF ORTHOPÆDICS: at 5.30 P.M. (Cases at 5 P.M.)
Cases: The following will be shown by—
Mr. Laming Evans (President): (1) Bilateral Synostosis of Radius and Ulna Associated with Bilateral Congenital Dislocation of the Hip; (2) Multiple Cartilaginous Exostoses Associated with Congenital Dislocation of the Hip.
Mr. A. W. Sheen: (1) Finger Joint Injury; (2) Autogenous Graft into Musculo-spiral Nerve.
Mr. H. A. T. Fairbank: Habitual Subluxation of Both Shoulders and Snapping of Both Hips, Associated with Unilateral Congenital Dislocation of the Hip.
Mr. A. H. Todd: (1) Chronic Arthritis of Knee in a Syphilitic Boy; (2) Tuberculous Disease of the Carpus in a Boy aged 9½ Years.

SECTION OF PATHOLOGY, at the Institute of Pathology, Charing Cross Hospital Medical School: at 8.30 P.M.
Mr. W. S. Cole and Dr. W. J. Adie: The Quantitative Analysis of the Gastric Contents.
Mr. W. S. Cole and Miss J. Aynton: Observations on Post-operative Ketosis.

Mr. J. E. Barnard: A Method of Demonstrating the Structure of Bacteria.

Dr. A. B. Rosher: The Agglutinins Present in Normal Sera for B. Enteritidis (Gaertner) and for Bacilli of the B. Suipestifer Group.

Dr. G. S. Wilson: Some Points in the Technique of Counting Viable Bacteria.

Dr. H. B. Weir and Dr. W. J. Adie: (1) Infarct of Spleen, followed by Rupture and Hæmorrhage; (2) Gumma of Heart with Hæmorrhage Causing Acute Heart-block.

Dr. W. W. C. Topley, Mr. J. E. Barnard, and Dr. G. S. Wilson: *A New Technique for Obtaining Bacterial Cultures from a Single Cell.*

Dr. W. W. C. Topley and Dr. H. B. Weir: Demonstration of the Lesions Found in Some Epidemic Diseases of Mice.

Dr. W. W. C. Topley: The Relation of B. Enteritidis (Gaertner) to Bacilli of the B. Suipestifer Group.

Friday, April 8th.

CLINICAL SECTION: at 5.30 P.M. (Cases at 5 P.M.)

Papers:

Dr. Ivor Davies: *Hair Ball or Hair Cast of the Stomach and* Gastro-intestinal Tract. A Report of Two Cases, with Specimens, and an Abstract of 108 Cases from the Literature.

Dr. M. Cassidy: Report re Case of Neoplasm of Lung.

Cases:

Mr. *C. Gordon Bryan*: Case of Osteitis Fibrosa, Treated by Resection of Four Inches of *Humerus* and Insertion of Boiled Beef Bone Graft.

Mr. Massie: Osteoma of Frontal Bone.

Mr. R. P. Rowlands: Two Cases of Jejunal Ulcer.

Other cases will be shown.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London *Hospital*, Hammersmith, W.

TUESDAY, March 29th.—10 A.M., Dr. McDougal: Electrical Department. 2 P.M., Mr. T. Gray: Surgical Out-patients. Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: *Skin Department.* 2.30 *P.M., Mr. Addison:* Visit to Surgical Wards.

WEDNESDAY.—10 A.M., Mr. MacDonald: Genito-Urinary Department. 2 P.M., Mr. Sinclair: Surgical Out-patients. Mr. Gibb: Eye Department. Mr. D. Armour: Visit to Surgical Wards. Dr. *Morton*: X Ray Department.

THURSDAY.—2 P.M., Dr. S. Pinchin: Medical Out-patients. Mr. Baldwin: *Orthopædic Department.* Mr. B. Harman: Eye Department. 2.30 P.M., Dr. A. Saunders: Visit to Medical Wards.

FRIDAY.—2 P.M., Dr. Burnford: Medical Out-patients. 2.30 P.M., *Dr. Pritchard: Visit to Medical Wards. Mr. Baldwin:* Operations.

SATURDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 2 P.M., Dr. Owen: Medical Out-patients.

Daily:—10 A.M. Ward Visits. 2 P.M., In-patient, Out-patient Clinics and Operations.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, 49, Leicester-square, W.C.

THURSDAY, March 31st.—6 P.M., Chesterfield Lecture:—Dr. W. Griffith: The Bullous Eruptions.

Communications, Letters, &c., to the Editor have been received from—

A.—*Answers*, Lond., Editor of; Dr. T. Adam, Stirling.

B.—Dr. C. W. G. Bryan, *Lond.*; Dr. H. W. Bayly, Lond.

C.—Dr. B. H. Cole, Lond.; Central Midwives Board, Lond.; Dr. R. *Craik, Lond.; Prof. E. L. Collis*, Cardiff; Children's Country Holidays Fund, Lond.; Mr. A. Cooke, Cambridge; Chelsea Hospital for Women, Lond.

D.—*Dr.* E. Drybrough-Smith, Shebbear; Mr. A. Daly, Lond.; *Dr. S. Delépine*, Manchester.

Notes, Short Comments, and Answers to Correspondents.

THE IDEAL ELEMENT IN MEDICINE, ILLUSTRATED BY THE LIFE OF JOHN HUNTER.

BY H. H. BASHFORD, M.D., B.S. LOND.

(*Concluded from p.* 635.)

The Growth of Medical Power.

EVEN *with the picture before us of the position of* Medicine in the year of Hunter's birth it is perhaps doubtful whether we have any of us quite realised how great that stride has been. In a world that every year is drawing its peoples closer, so that New York to-day has become nearer to London than was Hunter's Glasgow, in a world in which we now know the poet's phrase to be literally true that we cannot pluck a flower without troubling of a star, surely no *other art commands such faith or wields so various a power.* Upon the word of no other artist can an express train or an Atlantic liner be held up, the processes of law be delayed, or the engines of industry silenced; and yet by universal consent, as Kipling has reminded us, a doctor's certificate can do all these things. Not only in the sick room and the hospital, but in the every-day life of the school and factory, *in the building of houses and the planning of towns,* the community of to-day demands his presence.

The Doctor as Priest.

Even as the generals of *yesterday*, planning *a campaign*, consulted the oracles before *marching*, so the doctor is now called upon for his technical advice. Such and such a valley *is to be occupied,* but *the doctor prays down* his microscope, and the general, listening to his results, sends his men by another route. You have perhaps seen it stated indeed, *and with a good deal of truth, that the position of the* doctor *at the present moment is largely that of the mediæval* priest, out of whose side, as it were, he sprang. Where rich *men dying left in confidence* much of their wealth to the great monasteries, they now bequeath it in equal faith to the various hospitals. *That is a statement which Lord Knutsford*, for instance, would probably require me to qualify. But it is surely true that the community of to-day does recognise in the hospitals the expression *of a factor* inseparable from all true worship in its deepest sense.

Even in the ethical domain itself we behold the sphere of the doctor daily widening. More and more what was accepted as sin is now legitimately perceived to have been but ignorance, or the fruit of ignorance in the shape of *disease, ignorantly acquired or ignorantly unrecognised.* In many dark regions of human experience, where men once crept in moral fear, they may now walk, knowing the nature of their handicap, at any rate free from this particular burden. What that has meant in the rolling back of unnecessary clouds from the human conscience, what it has amounted to in terms of mercy and mutual forbearance cannot be guessed. But the result has been this, that to-day it is the doctor who has become the world's confessor, and whom the world *believes, rightly or wrongly, to have been the chief agent in* this spiritual enfranchisement. Health, wholth, wholesomeness, holiness—*more and more* has the world come to perceive that they are only facets of the same great crystal.

A Responsible Inheritance.

Such, then, is the inheritance to which the student of Medicine *finds himself called to-day*—an inheritance of such power and prestige as none of his predecessors ever entered upon. But, if there is one thing more than another that history has to teach us, it is that these are the very conditions most dangerous to idealism. Movement after movement, æsthetic and religious, has died *of its own material* prosperity, has attracted the professional, or professionalised the idealist, and perished from *fatty degeneration of the* heart; and it might be well *for us, just for a moment* or two, to take stock of ourselves from this standpoint. With increasing frequency, for example, it is being *openly alleged, not only that we are establishing a* priestly tyranny, but that this art of ours is becoming commercialised and that we are forming ourselves into *rings* to tax the *community.* That is untrue, of course, but at the same time it is, perhaps, a danger to be guarded against. In common with everybody *else we have been lately carried up* by an exceptional wave of idealism into an atmosphere of self-sacrifice, from which an apparent ebbing was probably inevitable. *I say "apparent"* because I firmly believe that behind *the new movements* that we are witnessing, behind the formation in almost every country *of group relationships* for *group-bargaining*, there is a sincere and honourable desire for a fairer and more joyous way of life.

the year. Legislation for making compulsory the vaccina*tion of children is being prepared, and a small hospital is* provided for in the Estimates. The medical officer considers that the Trengganu Malay has more faith in European surgery than in European medicine—the reverse of experience in the Western States of the Peninsula. There is no lunatic asylum. Lunatics, of whom there are many in Trengganu town, remain at large until discovered (by an overt act) to be homicidal; then they are confined by their relations in stocks or placed in the gaol, where they remain until they die or appear to recover. The proper treatment of insane persons is admittedly beyond the capacity of native rulers. In the State of Kedah the birth-rate was 30·04 and the death-rate 38·49 per mille. In the two preceding years the death-rate was 21·72 and 23·32. The State surgeon remarks:—

> "A comparison between the figures of the last two years shows the frightful havoc caused by the influenza pandemic. The Malay population suffered exceedingly, deaths amongst them rising from 4057 to 7859. Tamils suffered most severely, 1328 dying against 436, a nearly trebled death-rate, even allowing for the increase in Tamil population. The Chinese were much less affected, deaths being 1994 against 1660."

The principal diseases treated in the three principal hospitals of the State (Alor Star, Sungei Patani, and Kulim) were: Malaria, 1957 cases, 112 deaths; dysentery, 354 cases, 91 deaths; ankylostomiasis, 457 cases, 104 deaths; syphilis, 533 cases, 18 deaths; influenza, 552 cases, 134 deaths; and pulmonary tuberculosis, 143 cases, 76 deaths.

In the State of Perlis the birth-rate was 26·8 and the death-rate 31·1 per mille on an approximate population of 36,000. Influenza cast a gloom over the first two months of the year and took a toll of between 400 and 500 lives. No small-pox, plague, or cholera was reported.

Bahamas.—Mr. P. W. D. Ambrister, Acting Colonial Secretary, in a report just presented to Parliament, states that the birth-rate for the year 1919 was 35·7 and the death-rate 17·9 per 1000. The estimated population on Jan. 1st, 1920, was 57,838. The health of the colony in 1919 was good. No serious epidemic prevailed, but there were mild epidemics of influenza, German measles, and typhoid. The admissions to the General Hospital in 1919 numbered 742, making a total under treatment of 897, of whom 278 were discharged recovered, 288 relieved, and 36 unchanged, and 155 died. To the leper wards 5 males and 1 female were admitted, and to the lunatic asylum 24 males and 19 females.

INTERNATIONAL CONGRESS OF COMPARATIVE PATHOLOGY.

THE first congress took place in Paris early in November, 1912, under the presidency of the then Minister of Public Instruction, and was attended by more than 1200 members. The relation of human to bovine tuberculosis, and the changes to be found in the nervous system of rabid animals were two of the subjects which were fully discussed. A second meeting of the congress, as we had already announced, was to have been held in Rome at the beginning of April. Professor E. Perroncito, however, has announced on behalf of the organising committee the postponement of the congress, as the French delegates had intimated their unwillingness to meet German delegates without written acknowledgment by the latter of their responsibility for the European war.

UNDER-WEIGHTS IN MISSOURI.

A RECENT issue of the U.S.A. Public Health Reports records the inauguration in Missouri of "mother-and-child" nutrition clinics for the use of under-nourished children. When the school children in several cities were weighed and measured nearly half were found to be noticeably under-weight. In arriving at a decision as to what constituted an under-weight child the table of heights and weights prepared by Dr. Thomas S. Wood, of Columbia University, was used as the standard. A child who was found to be two or more pounds below the average weight for height and age, according to this table, was considered under-weight. The under-nourished child is one who is from 7 to 10 per cent. or more under the average weight for height and age according to the same table. He is not only below normal weight for height and age, but fails to gain at the normal monthly rate. During the period 8 to 12 years of age a boy should gain one-half pound per month; at 12 to 14 years of age he should gain three-fourths pound per month; and from 14 to 16 years he should gain 16 ounces per month. Under-nourished children fail to make these gains, and are, as a rule, pale, dull, listless, and under-sized. They become fatigued easily, and at times have no ambition for work or play. One of the most striking results of such a condition in children is their lack of resistance to acute diseases, and the majority of them suffer from catarrhal conditions of the respiratory tract. The under-weight children were examined and questioned in an effort to find the cause of the under-weight. It was found that these children had, besides physical defects, many faulty habits, such as late bed hours and insufficient or im*proper food consumption, which accounted to a great* extent for the fact that they were not gaining in weight normally. It was considered useless to try to correct these habits without the coöperation of the parents, and plans were worked out to secure this coöperation. Mothers of the under-weight children were invited to the school building to confer with the nutrition worker. Instead of the usual class work in nutrition mother-and-child clinics were held. The nutrition worker sat down with the mother and child and had a confidential talk about living habits. Much was got out which would not have been spoken in the presence of another woman. The prominent defects noted among these children are pale colour, winged scapula, and flabby muscle.

AN ACCIDENT DURING USE OF A HUMANE CATTLE KILLER.

ON March 4th a pony attached to a cart came into collision with a motor lorry at a road-crossing at Richmond. The animal was knocked over and its right fore-leg severely injured. The local inspector of the Royal Society for the Prevention of Cruelty to Animals was sent for, and upon arrival he decided to kill the pony. For this purpose he used the R.S.P.C.A. killer (figured as No. 3, p. 32, "Some Aspects of Humane Slaughtering," by R. O. Paddison, apparently published by the R.S.P.C.A., 105, Jermyn-street, London, S.W.). The inspector requested the police to clear the crowd away, and proceeded to put the nozzle of the killer on the pony's forehead and pull the trigger; death was instantaneous. Just as he was pulling the trigger three girls pushed to the front of the crowd at the side of the pony. As the crowd was dispersing one of these girls called out, "Someone has kicked me," and a few moments later, on examining the lower part of her leg, she found it was bleeding. When taken to the surgery of a local doctor, she was found to be suffering from a penetrating wound of the lower part of the leg about 4–5 inches above the ankle-joint; a piece of the stocking was carried in. Part of the bullet (roughly half), which had killed the pony, was extracted and she went home.

The condition of the girl is reported as satisfactory and whilst absent from her work she is receiving the amount of her wages from the R.S.P.C.A. Subsequent examination of the pony showed that when the cattle killer was fired the bullet struck the vertebræ of the neck and split, one portion remaining in the vertebræ and the other passing out at the back of the pony's neck and striking the girl. The inspector has stated that the instrument used was the only one he had, and was intended for use in slaughtering bullocks only. Since the accident he has obtained the Spearey killer (figured as No. 6 on p. 34 in the publication cited above) designed for killing horses, and will use it in future for this purpose. He further stated that he has had considerable experience in the use of the humane cattle killer; eight years ago on behalf of the R.S.P.C.A. he gave demonstrations all over the country from York to Penzance on the use of the instrument in slaughter-houses, using the same instrument employed at Richmond on March 4th. He had used the instrument for slaughtering "hundreds of beasts," and had never had an accident. Post-mortem examinations had shown that the bullet almost always flattens out in the "brain box," and he has never known a bullet to pass through a bullock's head. With a Greener killer, he states, the bullet has been known to come out of the hindquarters of a beast; there would seem to be some slight danger when this killer is used in slaughter-houses, if or when children are wrongly admitted during the slaughtering. According to the inspector 5000 R.S.P.C.A. cattle killers are in use; he has presented a full report of the accident to the society. The instrument used was apparently somewhat too powerful for this animal, which was only 13 hands in height.

An Investigation
INTO THE
IDIO-VENTRICULAR RHYTHM,
AND THE THEORY OF DISTURBED REFLEXES.

BY SIR JAMES MACKENZIE, M.D.EDIN., F.R.S.,
DIRECTOR OF ST. ANDREWS CLINICAL INSTITUTE.

INTRODUCTION.

IN investigating diseases in the human body it is difficult to obtain a clear line to follow. There is no lack of matter for inquiry, and there are plenty of perceptible phenomena which call for investigation. When I began my investigations many years ago I was aware of a curious aimlessness in my endeavours. I took up the study of symptoms and devoted much time to noting the individual peculiarities of a number. Thus the sounds of the heart arrested attention, and one studied with meticulous care their variations and the regions in which they were heard. Irregular hearts were the object of another inquiry, and the peculiarities of the graphic records were carefully studied, but no progress was made. After many futile attempts of this sort, I at last recognised that there was need for some clearly defined idea. Being engaged in general practice, I considered which points would be most valuable in practice. After some thought I concluded that two objects were necessary in practice—namely, (1) the mechanism by which a symptom is produced, and (2) the significance of that symptom in so far as it related to the patient's future life.

In dealing with the first of these objects I experienced much difficulty in finding a line to pursue. On various grounds my attention had been directed to heart conditions; I found irregular action of the heart of frequent occurrence, and I attempted to obtain an insight into the mechanism by which the different irregularities are produced. I followed for a time the practice already referred to of studying the records of the pulse-beats obtained by a Dudgeon's sphygmograph. At last it occurred to me that the irregularities seen in this way only showed what the left ventricle was doing, and the question arose as to what the auricle was doing.

This was one of those extremely simple and apparently self-evident conceptions which seem scarcely worthy of consideration, but which nevertheless bear within them the germ of a very fruitful idea; and it enabled me to obtain the first differentiation of irregularities based upon the laws governing the movements of the heart. I still remember, although it happened over 30 years ago, the occasion on which I obtained the first result of the application of this idea, in a record of an irregularity in which I was able to demonstrate that the ventricle occasionally contracted before the auricle—the ventricular extrasystole. I was led to apply the idea to other abnormalities which had baffled interpretation, and they in their turn became clearly defined. If we compare the knowledge of abnormal heart movements at the present time with that of 30 years ago the extent of the revolution that has taken place in the knowledge of this subject will be realised—a revolution that resulted from the application of the simple principle of finding out what the auricle was doing. No doubt many observers who have contributed to this revolution have carried on their work unconscious that this principle really lay at its foundation.

The same fundamental conception—the mechanism of symptoms—guided my inquiry into other phenomena of disease. Until lately only a limited success resulted, for the simple reason that there was no such clear principle for a guide. As the inquiry proceeded a better knowledge of a great number of the different signs and symptoms of disease was gradually acquired, so that it was perceived that there was some fundamental principle which governed the production of a large group of symptoms. It is now many years since this idea crystallised. When we opened an Institute for Clinical Research in St. Andrews we made the search for this principle our chief aim, and it was gradually revealed to us, although at first we scarcely recognised it because of its extreme simplicity; for we found *that the mechanism by which many symptoms are produced is due to the modification of reflexes that are normally present in the body.*[1] This theory of disturbed reflexes as the cause of symptoms of disease has begun to throw light upon many problems which we could not solve, and has afforded us a guide for the investigation into the early stages of common diseases.

The objects of this paper are: (1) to describe certain abnormal states of the heart in which the principle embodied is not the question of the action of the auricle during the irregular action of the ventricle, but the question of the action of the ventricle itself; (2) to demonstrate the application of the theory of disturbed reflexes in certain obscure cardiac conditions; and (3) to show the effect of an abnormal rhythm on the functional efficiency of the heart. This last object is of importance in order to understand that other matter essential to intelligent practice—the bearing of the cause of an abnormal sign upon the patient's future.

ABNORMAL HEART ACTION.

The following cases are illustrative of abnormal states of the heart.

CASE 1.—About 20 years ago, when I was attempting the differentiation of the various forms of irregular heart action, I singled out one peculiar form which I described in my book on the pulse, published in 1902.[2] It was a case of a woman, 35 years of age, eight months pregnant, who suffered at times from breathlessness, with irregular action of the heart. The irregularity was varied in character. Sometimes there were present ventricular extrasystoles occurring at rare intervals, and sometimes frequently. Occasionally groups of from two to six extrasystoles would appear, each group being separated by the appearance of a normal ventricular contraction; and occasionally there would be a long series of 20 or 30 of the abnormal ventricular beats, giving rise to a ventricular tachycardia. When free from the attacks of irregular heart action she felt well, but when the heart was irregular she felt breathless on exertion; I did not attend her in her confinement, but learnt that she came through it without trouble. I heard of her three years after as being in good health.

I explained the abnormal heart action as being due to premature or extrasystoles of the ventricle, occurring singly or in groups. Since that time other observers have described the same condition, and I have had a number of cases, some of which have shown other signs of considerable moment.

CASE 2.—Female, aged 57. Seen in January, 1919; complains of breathlessness coming on during the night and also on slight exertion; gives a history of having good health until 20 years ago when she began to have asthma, very slight attacks at first, but in later years they have become severe and more frequent; lately she has had periods of several months with attacks nearly every night. Up till ten years ago she was otherwise well and vigorous and able to do her usual housework and had no trouble in walking. Latterly she has become very breathless on exertion and can only walk a short distance. Pulse irregular, due to extrasystoles occurring singly and in groups; no jugular pulse. Heart slightly enlarged, the dullness extending out to the left nipple line. The sounds clear, chest slightly emphysematous, and no other abnormal sign could be detected. Digitalis was given, and two days' afterwards the pulse was quite regular. She continued to take digitalis as she thought that the heart's condition was better. She was able to continue her household duties, but gradually became weaker, with swelling of the legs and very distressing attacks of asthma in the night. From time to time record of the pulse was taken, and frequently the irregularity was present, always showing the presence of groups of extrasystoles.

On Jan. 21st, 1921, her state was as follows: Very spare, slight œdema of the legs, pulse irregular, due to the occurrence of an extrasystole after every second normal beat. The heart dullness half an inch beyond the nipple line, the sounds free from murmur. She is very breathless on the slightest exertion and suffers from great difficulty in breathing in the night. She has been taking digitalis during the last two years, taking 30 drops of the tincture a day. Digitalis was stopped; two months later the stoppage had produced no effect.

CASE 3.—Male, aged 56. Seen in January, 1917; brought to me by his doctor, who informed me that the patient was having an attack of angina pectoris in the waiting room. I had him brought in to the consulting room and found him suffering from pain of considerable severity, situated over the middle of the sternum. I felt his pulse and found it rapid and irregular, and took a long tracing, of which Figs. 1 and 2 are parts. Three minutes after Fig. 2 was taken he said he felt free from pain, and I took another tracing and found the heart had become quite regular, as shown in Fig. 3.

He gave a history of fair health until three weeks previously, when he began to suffer from attacks of pain lasting 3 or 4 minutes. Since then he has had a number of attacks; he says that they only occur when his heart becomes irregular; he is conscious of this irregularity. The doctor confirmed this statement. I found him a well-nourished full-blooded individual; heart only slightly enlarged; sounds clear, and blood pressure over 230 mm. Hg (see Fig. 4). The radial pulse, both during the irregular period and the regular period, showed the pulsus alternans (Figs. 3 and 4). There was a slight trace of albumin in the urine; specific gravity 1007. After this he suffered frequently from attacks of pain, but there were long periods when the heart was perfectly regular and he was fit for a fair amount of exertion. In spite of various treatments the attacks continued to recur until a year later, when he died during coitus.

CASE 4.—Male,* aged 58, seen May 26th, 1920. Complains of pain over left breast and breathlessness on slight exertion. Has lived many years in India and has suffered from malaria and attacks of diarrhœa for several years after 1896; otherwise a healthy man. He felt well and fit until January, 1919, when being engaged in severe bodily labour he felt a pain in his chest which became worse until he desisted from the heavy work. At this time the weather was cold and the pain was easily provoked when he walked out into the cold air. He went to bed for three weeks and for a few days the pain kept recurring, but gradually abated. The pain, however, ever since can be provoked with exertion, and particularly during periods of heart irregularity, of which he is conscious. At these times he is pulled up on walking 200 or 300 yards because of the pain; the latter is continuous, sometimes attaining a great severity, but never coming on in short spasmodic attacks; it is felt across the chest and down the inside of the left arm. When at his best, and when the heart is not irregular, he can walk from two to six miles on the level at a quiet pace. On an incline he is then pulled up by breathlessness and occasionally by pain.

On examination he is a well-nourished, healthy-looking man, though slightly sallow; heart enlarged, dullness extending one inch beyond left nipple line; a systolic murmur loudest at the apex; rhythm markedly irregular. A slight trace of albumin in the urine; an X ray examination showed nothing but a slight enlargement of the heart.

A tracing was taken of his radial and jugular pulses; it showed a very disorderly rhythm varying in a peculiar manner, of which Figs. 5, 6, and 7 are examples. The key to the irregularity is shown in Fig. 7, where the radial pulse shows a regular grouping of beats with one big beat followed by two small ones. The jugular pulse, however, shows an auricular beat perfectly regular in all three tracings. The small beats in the radial pulse are not due to normal ventricular contractions following the auricular beats, as can be seen from Fig. 6, where there are an irregular series of the small beats in the radial occurring at a greater rate than the auricular beats. From these tracings it is evident that the irregularity is due to ventricular beats independent of the auricular beats, except at the beginning of a group, where there is a large radial beat, which is seen to be preceded by an auricular wave.

Hitherto the cases of this condition I have seen were paroxysmal, and I had no clear idea of the treatment. Finding this arrhythmia was not paroxysmal but persistent, we put him upon digitalis (1 drachm per day) on May 29th. That night he was very ill, suffering from an attack of cardiac asthma and Cheyne-Stokes breathing, with pain across the chest. He speedily responded to the treatment, and the second day his pulse became at times slow and regular, as in Fig. 8, and at other times irregular, as in Figs. 10 and 11. As soon as his pulse became slow he felt remarkably well; pain disappeared, and he was able to take a considerable amount of effort without distress. The digitalis was stopped to see whether the improvement was due to the drug, and in a few days he was as bad as ever, the small beats tending to recur, as shown in Fig. 9. He was again put on digitalis and in a couple of days he was greatly improved; the pulse became slower, and many normal beats appeared, as in Figs. 10 and 11. He was told to watch the effect of the drug and to diminish the quantity when he felt very well, and take it just when he began to feel the slightest return of his weakness, so that he should regulate the quantity of his drug according to his condition. He continued well during the ten days he was under observation, and seven months later he wrote saying he was still very well and continuing to take digitalis.

Analysis of Tracings.

All the tracings given belong to the same kind of abnormal heart action. Those in Cases 3 and 4 show a well-marked auricular beat occurring at regular intervals, while the radial pulse is extremely varied in its rate and character. The irregular actions of the heart in all four cases belong to that group where the ventricle is the seat of disturbance. This can be inferred not only from the character of the tracings given here, but also from the electrocardiograms which have been taken from similar cases. I had an electrocardiogram taken of another case, and it showed that the beats during the irregular period had the character peculiar to ventricular extrasystoles.

In some tracings the irregularity has a superficial resemblance to that of auricular fibrillation (Figs. 5 and 6). During the abnormal periods in these cases, however, the ventricular beats are often quite regular (Fig. 2), whereas in auricular fibrillation, unless the heart is slow, there is a continual variation in the rhythm. Moreover, the electrocardiogram of auricular fibrillation shows the ventricular complex to be normal in its character, indicating that the stimulus for the ventricular contraction comes from the auricle, while the ventricular complex during the abnormal rhythm in these cases correspond with that of a ventricular contraction arising in the ventricle itself, so that these cases belong to a group where the abnormal rhythm is ventricular in origin.

Heart Failure.

These four cases are of further interest as showing the signs characteristic of heart failure. Heart failure cannot be detected by examination of the heart itself, but only by the effects of impaired supply of blood upon the other organs of the body. Dropsy and enlarged liver—sometimes spoken of as the cardinal signs of heart failure—only occur in relatively few cases; the vast majority of people who suffer from heart failure never show these signs.

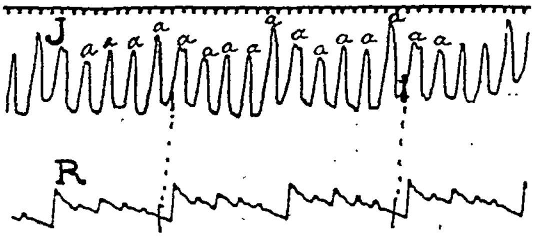

FIG. 1.—Part of simultaneous tracings of jugular (J) and radial (R) pulses, slightly reduced. The waves (*aa*) in jugular tracing are due to the contraction of the right auricle, and are quite regular, in contrast to the irregular rhythm shown in the radial tracing. The radial beats occur in groups of five, the first of which is a normal beat and arises in response to an auricular contraction, while the other four beats arise in the ventricle, independent of the auricular beats, and at a slightly more rapid rate. The characters of this irregularity are better brought out in Fig. 2.

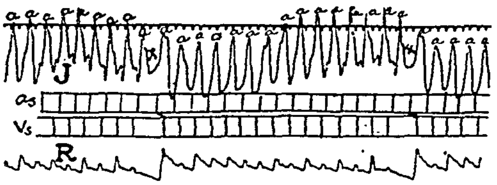

FIG. 2.—Part of simultaneous tracings of jugular (J) and radial (R) pulses reduced to $\frac{2}{3}$. The waves (*aa*) in the jugular tracings are due to the contraction of the right auricle, and are quite regular in contrast to the irregular rhythm of the radial pulse. The radial beats occur in groups. In Fig. 1 the groups were of five beats; in other instances they were 19, 13, and 15, as in this tracing. The first beat of the group is a normal beat in response to an auricular systole. In the intercalated diagram the downstrokes, As, represent the auricular waves in the jugular, while the downstrokes, Vs, represent the radial pulse (ventricular systoles). The space between represents the passage of the stimulus from auricle to ventricle, and it is shown this only occurs with the first beat of the group, all the other radial beats (ventricular systoles) being independent of the auricular systoles. At the end of each group there is a pause before the appearance of the normal ventricular contraction. It is interesting to note the appearance of the pulsus alternans. The beat after the first large beat of the group is always small, then the alternation is at first slight but becomes more marked towards the end of the group. There is no very clear evidence showing that the ventricular rhythm had any effect on the auricle, although there is a suspicion of a lengthening of the pause at ×, between the beats that precede the beginning of a group. Moreover, as soon as the abnormal rhythm ceased the auricular rate fell from 130 (as in this tracing) to 120, as in Fig. 3, suggesting that the auricle was affected.

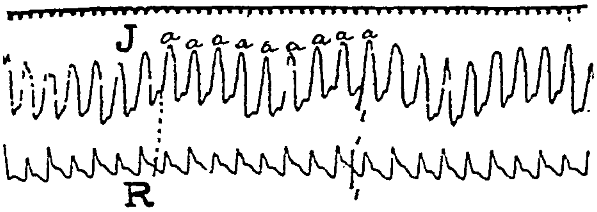

FIG. 3.—Simultaneous tracings of jugular (J) and radial (R) pulses, taken three minutes after Fig. 2. The radial pulse is now regular in time, and each beat is preceded by an auricular systole, showing that the rhythm is now normal. The rate is 120 per minute. The radial pulse shows the pulsus alternans—the rhythm being quite regular, while a large beat alternates with a smaller.

The best method, in fact the only method for obtaining a knowledge of the heart's efficiency in a person who is able to get about, is by appreciation of response to effort. This knowledge can be obtained not by any form of exercise in the doctor's consulting room, but by eliciting a clear account of the manner in which the patient responds to those efforts made in his daily life where the circumstances cannot be imitated by any artificial method, such as the sensations experienced on walking up a hill, or on walking after a full meal or in the cold air. When there is impaired efficiency of the heart these experiences give rise to certain very definite sensations, and these sensations are of the nature of disturbed reflexes. Thus the vast majority of people whose heart's efficiency is impaired suffer at times from one of two kinds of sensation, breathlessness or pain, with their accompanying sensations. In breathlessness the respiratory reflex is disturbed, and in pain the viscero-sensory reflex peculiar to the heart is disturbed.

---

* I am indebted to Dr. R. L. Girdwood for most of the notes and records of the effect of the drug in this case.

It is unnecessary to dwell upon breathlessness as an evidence of heart failure, although the exact portion of the reflex arc disturbed is still far from clear. The disturbance of this reflex is not direct from the heart, but because the heart fails to supply the respiratory system with the normal kind of blood.

The nature of the reflex which gives rise to pain can be inferred by the situation of the pain, its peculiar distribution, and the phenomena which accompany it. I need not go into this matter more fully here beyond stating that the group of symptoms which accompanies the pain are the result of a stimulus arising from the heart muscle. The researches which we have been carrying on for some time show that there is a definite series of phenomena provoked by muscular fatigue, and the principle governing the appearance of these phenomena are the same for the heart as for other muscular organs.

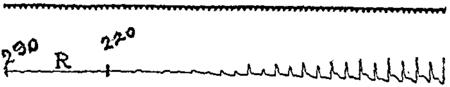

FIG. 4.—Part of tracing of the radial pulse (slightly reduced) while the blood pressure was being taken. The cuff embracing the upper arm was distended till the pressure was over 230 mm. Hg and the radial pulse was recorded. The air was allowed to escape and so the pressure within the cuff fell, the radial pulse gradually appeared—first the big beats, at 230, and the smaller beats at 220. This method brings out the distinctive features of the pulsus alternans.

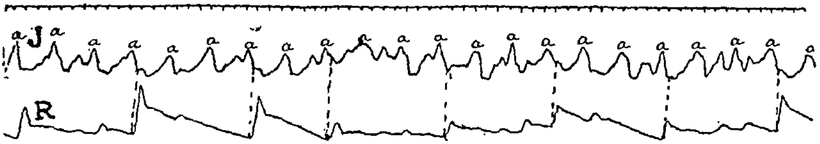

FIG. 5.—Part of simultaneous tracings of jugular (J) and radial (R) pulses, slightly reduced. Shows a very disorderly irregularity of the radial pulse, while the auricle (waves a) is regular auricular rate 90 per minute. The large beats in the radial are due to ventricular contraction arising in the normal manner—i.e., as a result of a stimulus from the auricle. The smaller beats are idio-ventricular beats, arising in the ventricle. There is a tendency for the ventricular beats to occur in groups. (May 26th, 1920.)

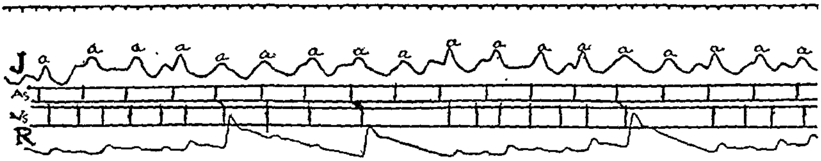

FIG. 6.—Simultaneous tracings, slightly reduced. Shows the same as Fig. 5; the tendency to form groups is more marked though the beats vary in number. Auricular rate 86 per minute.

In the cases described we find present one or both of these phenomena, breathlessness and pain. In the young woman (Case 1) there was breathlessness only, and also in Case 2 breathlessness was the only sign. In Case 4 there was both breathlessness and pain, and in Case 3 pain was the dominant symptom. In the vast majority of people in whom pain occurs it only takes place when the heart is called upon to make an effort; in Cases 3 and 4 pain occurred without effort, manifestly because the abnormal rhythm itself was an embarrassment to the heart in its work. In the case of the young woman the abnormal rhythm embarrassed the heart, for she could take effort without distress when free from the abnormal rhythm, but was easily rendered breathless when it was present. Pain in Cases 3 and 4 was of that dull prolonged kind, different from the pain of angina pectoris, when it occurs in definite attacks and subsides on the cessation of effort. In some respects the pain is like that which is occasionally present in auricular fibrillation. In this condition attacks of angina pectoris rarely occur. Patients who may have suffered from attacks of angina pectoris when the rhythm was normal become free from them when auricular fibrillation appears. One reason for this fact is that whereas effort provokes pain in patients with a normal rhythm; during auricular fibrillation, breathlessness occurs so readily that they are pulled up from this

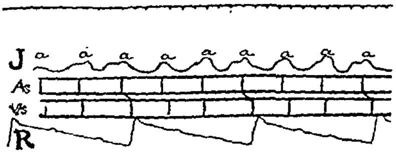

FIG. 7.—Part of simultaneous tracings (slightly reduced), taken at the same examination as Figs. 5 and 6, and showing regular groups consisting of one normal beat followed by two extrasystoles, the auricular rhythm being unaffected. In the intercalated diagram the downstrokes in the upper spaces, As, represent the auricular systoles (waves a in the jugular tracing), and in lower space, Vs, the downstrokes represent the ventricular systoles—represented by the radial beats. The space between represents the passage of the stimulus from auricle to ventricle, and it is shown only to occur with the large radial beats—the smaller beats occurring independent of the auricular contraction. The auricular rate is 88 per minute. (May 26th, 1920.)

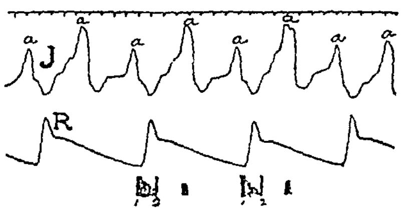

FIG. 8.—Part of simultaneous tracings (slightly reduced), after the administration of two drachms of tincture of digitalis. The auricular waves a in the jugular are 72 per minute, while the radial pulse is 36. During the pause in the radial pulse an extra-systole occurred, so weak that it is not shown in the radial tracing. On auscultation a single sound was heard during the pause which is shown diagrammatically under the radial tracing. The auricular waves during the pause in the radial beat are larger than the one which preceded the radial beat. The reason for this is that at the time the auricle contracted the ventricle was in systole, so that the contents of the auricle could not be emptied into the ventricle, but are forced back in the jugular.

cause. Nevertheless, in some cases, particularly where the heart is persistently rapid, pain of considerable severity may be felt across the chest, and it may disappear when the heart becomes slow under the influence of digitalis.

THEORY OF DISTURBED REFLEXES APPLIED TO THE ACTION OF DRUGS.

The theory of disturbed reflexes throws a new and unexpected light upon the action of digitalis and other cardiac drugs. It had been recognised for over 100 years that digitalis at times caused great slowing of the heart's action; consequently, the drug was supposed to be indicated whenever there was an increase in the heart's rate. It was found, however, that the slowing only occurred in a few cases. An inquiry into this difference enabled me to point out in 1906 that this slowing only occurred in people with an abnormal rhythm, particularly in those conditions which we now recognise as auricular fibrillation and auricular flutter. Although these observations have been fully confirmed, no clear understanding of the reason could be given. We are now able to give the explanation. In the vast majority of people who have a rapid action of the heart there is present some disease which produces agents that act upon the cardiac reflexes. Thus, in febrile states, such as pneumonia, influenza, and measles, the heart is usually rapid, sometimes very rapid, because of the action of the toxins of those diseases upon some portion of the cardiac reflex. When digitalis is given in such cases no effect is produced because the reflex is already poisoned by an agent which the digitalis is unable to overcome. The rapid pulse in auricular fibrillation and in the idio-ventricular rhythm described in this paper is due to a totally different cause. In auricular fibrillation it is the shower of weak stimuli from the fibrillating auricle which causes the increased ventricular rate. While in this form of independent ventricular rhythm which we are discussing the increased rate is due to some agent in the ventricle itself quite apart from the reflex. The digitalis, therefore, is acting in these cases upon a reflex not disturbed by any other toxic agent.

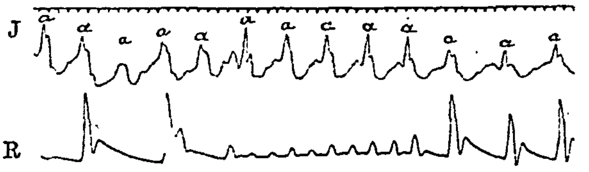

FIG. 9.—Part of simultaneous tracings (slightly reduced), taken four days after the stoppage of digitalis; the patient's condition became worse and the pulse became rapid and extremely irregular, with periods of rapid ventricular beats. Auricular rate 74. (June 7th, 1920.)

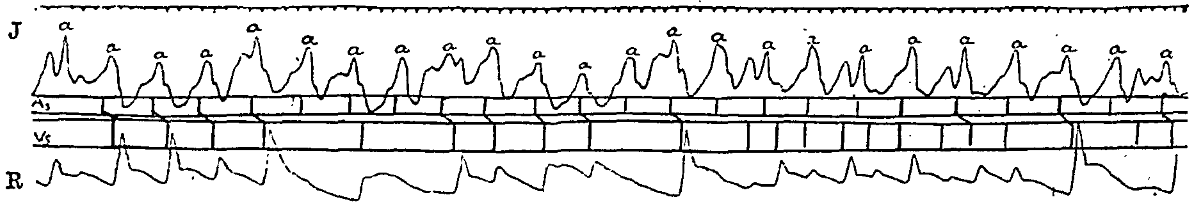

FIG. 11.—Simultaneous tracings (reduced to $\frac{3}{4}$) taken on the fifth day of digitalis administration, the patient's condition still showing signs of improvement. The tracing represents a period of great irregularity, which the intercalated diagram shows are due to the erratic appearance of ventricular extrasystoles. Auricular rate 72 per minute. (June 13th, 1920.)

It is known that a stimulation of the vagus has a distinct effect in dulling the auriculo-ventricular conducting system, and it is probably on this account that digitalis slows the heart in auricular fibrillation. But this is not the explanation which causes the slowing in this ventricular tachycardia. The researches of Gaskell[3] show that the stimulation of the vagus has a very definite influence upon the various functions of the heart muscle fibres, and it is probable that the digitalis effect in Case 4 was due to some such action. It is to be noted that the slowing of the heart was more rapidly produced in Case 4 than in auricular fibrillation. It takes from 4 to 7 drachms to get a definite effect in auricular fibrillation—the patient taking 1 drachm per day. In this patient the effect seemed to be produced after 2 drachms. Support of this view is found in the absence of effect on the auricle. The auricular rate fell from 86 to 72 on first taking digitalis. The auricular rate did not rise above 72 when the digitalis was stopped while the ventricular rate increased. The resumption of the digitalis speedily affected the ventricle but did not affect the auricular rate (see Figs. 5, 6, and 7). I recognise, however, that more observations will have to be made before this susceptibility is proved. There is a point of resemblance in the recovery from heart failure between auricular fibrillation and this ventricular rhythm in that the diminution of the ventricular rate seems the chief agent in restoring the heart's efficiency, more time being given after each systole for recovery.

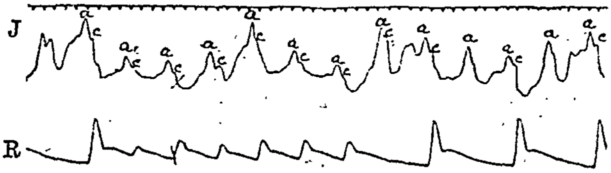

FIG. 10.—Part of simultaneous tracings (slightly reduced), taken four days after resuming the digitalis; the series of small ventricular beats had ceased, though the rhythm was still irregular. This tracing shows a group of normal beats, and periods when the radial pulse had only half the frequency of the auricular rate, as in Fig. 8, and for the same reason. Auricular rate 74 per minute. (June 12th, 1920.)

Sutherland[4] has shown that certain hearts with a rapid rate and the normal rhythm are susceptible to digitalis. This observation does not invalidate the view expressed here; it merely shows that there are agents which increase the heart's rate and which the digitalis can overcome.

PROGNOSIS.

In the investigation to which I refer in the introduction I spoke of the principles which guided me in detecting the mechanism by which symptoms are produced. Another matter absolutely essential to intelligent practice had to be considered—namely, what happens to the patient who shows an abnormal sign. This matter of prognosis is one that has been greatly neglected. While investigation into the various forms of cardiac irregularity has added greatly to our knowledge, such knowledge can only become of real practical use if it is supplemented by the knowledge of what effect the cause of these irregularities has upon the heart's efficiency. The great question, therefore, in every case is, Does this sign indicate heart failure or does it foreshadow its oncoming? It has been rather hastily assumed that this kind of knowledge was so easily acquired that no special steps should be taken to find it out. In reality it is a subject of very great difficulty, and requires a particular method of observation which very few people have undertaken. To begin with, to be able to undertake an inquiry into prognosis it is necessary to have a knowledge of the symptoms of heart failure; and so far very little has been done to discover what these are, for a great many signs which have no relation to heart failure have been mistaken for signs which gave that knowledge.

An investigation into this subject has revealed the fact that no physical sign or peculiarity of the heart itself can ever give the information as to its functional efficiency. The presence of some cardiac signs may be recognised as associated with heart failure, but they themselves are not signs of heart failure, so that one can say that no single abnormal sign is of itself a basis for prognosis.

Many years ago, on looking up my cases of pulsus alternans, I found that they had all died, and the question arose, Was this a sign of grave moment? A prolonged investigation revealed that when it was of grave prognostic significance there was always a great limitation of response to effort. It was occasionally present when not associated with any form of heart failure, as in certain forms of paroxysmal tachycardia, or when an individual had suffered severe pain such as hepatic colic. On the other hand, when this sign is present and indicates a grave prognosis, it is invariably accompanied by a great limitation of the person's response to effort, that is, effort evokes sensations of breathlessness or pain with great facility.

The reason that I have quoted the first case is to show that this ventricular rhythm may be present and the patient be in no danger, while its presence in Cases 3 and 4 shows that while it may embarrass the heart it is not of itself necessarily a serious sign—that is to say, the heart muscle itself was manifestly impaired, and the presence of this abnormal rhythm further embarrassed the heart in its work. The presence of pulsus alternans in Case 3 was of grave significance, but there was present such a degree of functional inefficiency that the slight embarrassment induced by this abnormal rhythm immediately caused great suffering, and the outcome of the case justified the view that the patient's condition was a grave one.

MEDICO-MILITARY TRAINING.

BY H. E. R. JAMES, C.B., C.M.G., O.B.E., F.R.C.S. ENG.,
LIEUTENANT-COLONEL, R.A.M.C.

IN introducing the subject of the best form of instruction for medical students to fit them to take their part in case of national emergency, I would first postulate that the Officers' Training Corps, which has fully established itself and is completely organised, should be accepted as the organisation under whose ægis the training should be carried out. Its machinery is complete and it has come to stay. The national emergency is, of course, war, but there are many minor emergencies which may be encountered, even in the course of civilian private practice, in which a training calculated primarily to make a medical practitioner fit for field service as an army medical officer will be found of value, particularly to a medical man who enters any form of State medical service. Secondly, the training must be carried out in the leisure time of the student. The present medical curriculum, calculated to make a student efficient in carrying out duties to the sick in civil life, is sufficiently intense and exacting to make it unfeasible to add compulsory auxiliary subjects to those considered essential. Thus the training must be voluntary. It takes up time which the less patriotic or provident student devotes to games. Therefore the instruction should be as recreational as possible, and calculated for the mental enlargement as well as the physical culture of the student. It should be adapted to serve him in whatever course he adopts, as far as is compatible with its main object.

Origin of the Officers' Training Corps.

The medical units, Officers' Training Corps, form one of the branches of the senior division of that body, of a specialist type. For the information of those who have not been brought into touch with the subject of the Officers' Training Corps it may be well to state shortly its nature and functions.

It was formed in 1908 during the Secretaryship of State of Lord Haldane by a committee of school and university teachers, under the chairmanship and guidance of Sir Edward Ward, then Permanent Under Secretary of State for War, with the object of giving a standardised measure of training in military matters to students at schools and universities such as would fit them to become officers of the army, S.R.O., and T.F. It absorbed existing volunteer corps at schools and universities and consists of junior and senior divisions—the junior division at public and other large schools, the senior division at universities (and the Inns of Court). The officers in the junior division are schoolmasters, in the senior division members of university staffs, and both are on the Unattached List of the Territorial Force.

In the junior division, with the exception of two schools, where some engineer work is taught, infantry training alone is given. In the senior division, although infantry training is their staple, units of cavalry, artillery, engineers, signals, R.A.S.C., R.A.M.C., R.A.V.C. are formed and the special duties of these branches are taught in units of the contingent, of the formation of corresponding units in the army. The training is carried out under the general supervision of chief of the Imperial general staff, by the officers of the several contingents in term time and in annual camps. Adjutants who are attached to the general staff are appointed from the Regular army to contingents, and N.C.O. instructors are supplied. Equipment, arms, and uniform are also found by the public in kind or from grants. Cadets serve under a contract with their universities; they are not subject to military law, and enrolment is voluntary.

The affairs of university contingents are administered by a military education committee of the university where they exist, and the War Office assists the committee as necessary in carrying out their work. A certain minimum number of instructional parades are necessary to qualify for efficiency. Annual camps are held, and the training is made as practical as possible to fit the cadet for war service conditions. Certificates are obtained by examination.

One year of training is the minimum to admit a cadet to sit for Certificate "A," and two years for Certificate "B." Only Certificate "A" is obtainable in the junior division; both "A" and "B" are obtainable in the senior division. The possession of these certificates gives the holder certain definite privileges if he should choose the military career.

But the real value of the organisation is that it disseminates military knowledge among a large body of the class of men who are best fitted to hold commissions, and prepares them to take their places as officers in time of emergency, with a minimum of preliminary instruction. The Officers' Training Corps comprises a very large body. Twenty-one contingents exist in the senior division, and 162 in the junior division. The value of the training was fully proved in the war. Had it not been for the Officers' Training Corps output it would have been impossible to supply the army with junior officers. It is not too much to say that it saved the situation at the beginning of the war.

The Medical Units of the O.T.C.

These units have been formed of medical students, as units of the senior division contingents, with a view to training them for the Military Medical Services. The training unit is a section of a field ambulance, that being the war unit which gives the best opportunity of visualising the functions of the medical service in the field. Such units have been formed at the Universities of London, Cambridge, Oxford, Dublin, Belfast, Edinburgh, Aberdeen, and Glasgow, at which centres the larger medical schools are located. It is hoped that other units may be formed at other medical schools, but this cannot be sanctioned at the present crisis in national financial affairs.

Before proceeding with details I may state that some 5000 medical students were trained prior to the war in these medical units. A proportion of them took commissions in the Special Reserve and Territorial Force. The remainder, all such as were qualified, served in the capacity of medical officers in the navy or army, and the value of their O.T.C. training was testified to both by the officers whose commands they joined, and under whom they served, and by themselves. The value to the army of this body of trained medical officers was immense; and here I would insist that it is not enough for a medical man, in order to develop his full usefulness in the Army Medical Service, for him to be in possession of a medical qualification, and to have added a measure of military science, whether during a course at a training centre or in another arm of the Officers' Training Corps than his own. It is true that a knowledge of discipline and leading, and the action of other arms in addition to his medical qualification, will make some sort of an army medical officer, but it is not quite to the point, because the Army Medical Service is a highly specialised branch of the medical profession, and although its primary function is to aid the fighting power of the army by keeping the largest possible number of soldiers fit to fight, yet its essential aims are of a conservative kind, whereas in the fighting branches they are all destructive. The two points of view are essentially opposed to each other and the training shapes the mind to one or other aim. Moreover, it is a waste of time and money to train a cadet whose services would be certainly best, and perhaps only, used in war in the medical service, in the work of a fighting arm, and vitiates his point of view. There is enough of important military medical knowledge to be acquired with advantage throughout the whole of a medical cadet's training in a medical unit to take him all his training period to assimilate. This work has a direct bearing on his duties as an army medical officer. It is such as is not acquired during his purely medical curriculum, though much of it would aid him in his civil practice, such as sanitary and administrative work. And the method of its conveyance is far superior to that of a condensed course such as that undergone at a training centre, as it is spread over a longer period and given in assimilable doses.

There is another most important advantage in the existence of a medical unit at a university which is that it keeps the Army Medical Service in the eye of the public of the university. The Army Medical Service in time of peace is a body little known to such public, and from time to time good students have not only not been encouraged to join but actually discouraged by their teachers from doing so. The late war has been responsible for bringing the work of the corps to the knowledge of the medical profession, and there exists a very large body of medical men who have been trained in war and who may be counted as available for service in case of emergency for a few years. But the Officers' Training Corps is for the purpose of training the young men during their university education, and is a provident institution. It is the only piece of mechanism in this country that provides a reserve of potential medical officers for the army, and for this reason alone it deserves all the encouragement it can get.

Course of Training.

The course of training, as has been said, is shaped to fit the medical student on his becoming qualified to undertake the duties of a junior officer of the Army Medical Service in the field, with the least expense of time, or even with no preliminary training at a centre, and to make him as nearly as is possible in the time equal in essential matters belonging to war conditions to the young medical officer of the Royal Army Medical Corps. He cannot, naturally, have an equal knowledge of hygiene, tropical diseases, drill, discipline, interior economy, &c., in which the Royal Army Medical Corps lieutenant has had a six months' course at Aldershot and the Royal Army Medical College, and to which all his time has been devoted, but he will have gained enough to enable him to grasp the ideas underlying his work, its general direction, and many of its necessary details.

The course given to enable the cadet to enter for Certificate "B" lasts for at least two years; for Certificate "A" one year. During the first year, before he has entered upon the professional subjects of the medical curriculum, such as surgery and medicine, he is taught the military part of his duties and a certain amount of elementary sanitary work, and such portions of the work of a medical officer as do not involve the knowledge of his medical specialty. The cadet of the infantry is at this time learning to be a platoon leader, and the medical cadet acquires such knowledge of squad and company drill and ambulance drill, map-reading, and elementary military law as will make him efficient in the matter of leading and commanding the men who will be committed to his charge in parallel with him.

He also learns bandaging and the application of splints and tourniquets, field dressings, the contents of the medical panniers, means for the purification of water for the troops, tent pitching, field cooking, and the construction of extemporised structures used in camp sanitary conservancy, in which particulars he has to instruct his men. During the annual camp he puts them into practice. He receives instruction in the outlines of army and army medical organisation by lecture, in order that he may appreciate his particular sphere of activity and his responsibilities as an army medical officer. He has to attend a fixed number of instructional parades and the annual camp to attain to being "efficient." He supplements such instruction by a study of certain text-books of regulations.

Before sitting for Certificate "B" he undergoes a second year at least of Officers' Training Corps teaching of a kind which involves some knowledge of medicine, surgery, and hygiene, and medico-military details to a more particularised extent. This is intended to fit him to act as a medical officer in charge of a unit other than medical, and as a junior officer of a medical field unit. It involves training in organisation and administration, a knowledge of the structure and functions of medical units, military law, hygiene, including prophylaxis against diseases of armies, and methods of disinfection of buildings and clothes, and of water purification, personal hygiene and prevention of disease, under which come various agencies in the causation of disease, methods of disinfection and sterilisation and disinfestation in the field, sanitary survey of places frequented or used by troops, means of transport of sick and wounded, improvisations to supplement existing conveyances, the medical aspect of marches, quarters, movements of troops by rail and sea, and housing, feeding, and clothing of troops.

Opportunities for physical training exist in contingents and cadets are encouraged to learn to ride where there are facilities for it. Instructional stores are provided at contingent headquarters, being specimens of the vehicles, tentage, and ordnance, and medical stores of a field ambulance, for use in demonstration and practice during term-time. In the annual camp, which the cadet attends for eight days at least, the unit obtains from the command in which the camp is held vehicles and horses and stores to make it up to the establishment, and it is exercised on a scheme devised to demonstrate its working under war conditions. During term-time, when possible, tactical schemes may be carried out to illustrate the interworking of the unit with other units and arms.

Objects of Medical Cadet Training.

The whole training is designed to give the cadet a comprehensive outline of the work of any army medical officer in war, with as much useful detail as possible, and to enable him to instruct his subordinates. He must know enough of discipline and procedure to relieve him from embarrassment on entering his new sphere and to develop his full usefulness, enough of drill to enable him to move his men correctly and give him confidence, and enough of interior economy to enable him to deal with matters concerning the comfort and well-being of his men and patients.

The advantages of such training are, from the point of view of the State, considerable, in that it provides a reserve of potential medical officers possessing an amount of knowledge of the duties they would have to perform in war adequate to make them of the fullest value from the time of their joining, and this is fully realised. The advantages to the cadet are also considerable; he acquires, at no expense to himself, except that of some of his leisure time, an insight into subjects which in the event of his joining a State Medical Service are of supreme value, and, should he take up private practice, will fill gaps in his ordinary curriculum and be found very useful.

These are: a practical view of elementary hygiene which makes a good groundwork for its more intimate study; practice in first-aid methods and in the transport of sick and wounded and in improvisation in this connexion; organisation and methods of administration which enable him to deal with masses, as in railway accidents, mine disasters, &c., and to conduct his affairs with method; discipline, which will serve him in all the amenities of life and in dealing with subordinates. Map-reading is an accomplishment of practical use in everyday life, and its application to surveying and inspection will be found very useful by a medical officer of health. Drill and ambulance drill put him in the way to direct his assistants in the carrying out of any combined operation, such as the placing a patient upon a stretcher or in a vehicle. In addition to these pieces of knowledge the cadet gets an annual airing in camp at no expense to himself, which is most beneficial to his health. He is a member of a corporate body within the university, and his social relations with his comrades are of the most pleasant and healthy kind. To the university in whose Officers' Training Corps contingent he serves the organisation is of value in the fact that it has a body of students bound together by the ties of discipline and comradeship, who are working with a high aim for the welfare of the State, and who set the best kind of tone in the university, and influence others by their example. In a non-resident university this is particularly valuable. The training fosters habits of punctuality and the realisation of duty and responsibility.

War Record of the Medical Units.

The war record of the medical units is a very fine one and has amply established the value of the organisation and training. Unfortunately records are not complete, but of a body representing about a quarter of the whole number of medical officers of all services and categories who trained in these units—Royal Naval Medical Service, Royal Army Medical Corps, Special Reserve of Officers, Territorial Force, and temporarily commissioned officers—1178 in number, whose records have been obtained, 95 gave their lives, 176 were decorated, and 114 mentioned in despatches, a testimony to their devotion and efficiency and an example to the rising generation of students.

Their Present Position.

At the present time the senior division of the Officers' Training Corps, and particularly the medical units, are at a low ebb. For this there are several reasons:—

(1) A general feeling of war weariness and an idea fostered by the hope that there will be no more war in the near future.

(2) The fact that most of the present generation of medical students have served and do not feel disposed to give their leisure time to further military training under peace conditions. This reacts upon the younger men who were not of military age during the war.

(3) Certain very acute grievances which affected those former cadets who had taken commissions in the Special Reserve of Officers and Territorial Force during their war service. Of these grievances, the most poignant was (*a*) the better rates of pay accorded to medical men who took temporary commissions at consolidated rates of pay—24*s.*—the Special Reserve of Officers and Territorial Force officers only getting 20*s.* at the maximum, inclusive of their allowances which they dropped when on leave or in hospital; others were (*b*) the reluctance experienced in the granting of temporary rank to Special Reserve of Officers and Territorial Force officers, as compared with temporary officers, owing to the fact that seniority lists in the Special Reserve of Officers and Territorial Force were adhered to and were of a permanent nature, whereas on demobilisation temporary officers would be clear of the military establishment; (*c*) the ignoring of the previous training of Officers' Training Corps cadets on posting, due to the anxiety and hurry of mobilisation.

(4) During the war it was compulsory upon all students who were held to continue their studies, or who were physically of low category and for these reasons not called to the colours, to join the Officers' Training Corps. This brought a number of reluctant men into the medical units. The reversion to the voluntary system was the signal for these men to break away.

(5) The fact that those who had had their studies interrupted during the war felt it necessary to give the whole of their time to professional work and to make up the time lost in preparing themselves to earn their livelihood in civil life.

(6) A doubt as to whether it is worth while, and a question as to the tangible advantages to be drawn from the training.

Measures Enacted to Remedy Grievances.

The remediable causes of disinclination have after representation been remedied, and the following measures enacted:—

(1) In future all commissions will be in the Special Reserve of Officers or Territorial Army; this abolishes the giving of temporary commissions carrying higher rates of pay, and avoids the setting up of a standard of comparison which was so unfavourable to Special Reserve of Officers and Territorial Force Officers under former conditions.

(2) Six months' seniority will be given to officers who on joining the Special Reserve of Officers and Territorial Army possess Officers' Training Corps Medical Certificate "B," and three months to holders of Certificate "A."

(3) A credit of 6 per cent. of marks to holders of Medical Certificate "B" and 3 per cent. to holders of Medical Certificate "A" will be accorded at the entrance examination to candidates for Royal Navy Medical Service and Royal Army Medical Corps.

(4) Preference in the matter of posting and promotion will be given to officers in possession of Officers' Training Corps certificates over those who have not trained who apply for service in the medical branch of the army. Card records of the Officers' Training Corps services of medical cadets are now kept by the D.G.A.M.S. for reference.

The other causes of reluctance should in time cure themselves, provided always that encouragement at the medical schools is given to students to undergo their training.

THE TREATMENT OF INFECTIOUS DISEASES BY LEUCOCYTOLYSIS

PRODUCED BY RONTGENISATION OF THE SPLEEN.

BY IVAN I. MANOUKHIN, M.D.

(From the Institute of Experimental Medicine, Petrograd.)

IN my thesis "On Leucocytolysis" (Petrograd, 1911) I proved by direct experiments that an organism combats infection mainly by means of the breaking-up of its leucocytes. If in many acute infectious diseases there is an increase in the number of leucocytes in the blood, I regard this phenomenon as preparatory to their subsequent breaking-up. The organism can only cure itself when the specific anti-substances produced by the leucocytes have come out from them and filled the blood plasma, as a result of leucocytolysis. This process is produced in the blood by special soluble ferments entering into it, which I proposed to call "leucocytolysins," and leucocytosis, in those cases when it precedes leucocytolysis, is produced by soluble ferments, whose properties are opposed to those of the leucocytolysins, and which I proposed to call "antileucocytolysins."

Later on I succeeded in proving that leucocytolysins are produced by the spleen, and anti-leucocytolysins by the liver.[1]

From that moment it became possible to verify the correctness of the above theory in practice, and in 1913 in Professor Metchnikoff's laboratory at the Pasteur Institute in Paris I carried out with this purpose the following experiments. I infected with human tuberculosis monkeys (*Macacus cynomologus* and *rhesus*) and guinea-pigs, which are very susceptible to tuberculosis, and I stimulated artificially in them the activity of the spleen so that leucocytolysins should appear in the blood and that the leucocytolysis caused by them should exercise its curative effect. The stimulation of the activity of the spleen was carried out by radiating the organ with small doses of Rontgen rays. On this method, which is now being widely applied to men, I shall dwell in more detail as follows.

Method of Radiation.

The human spleen is radiated by a dose of X rays equal to 1 h., as measured by the Sabouraud and Noiré radiometer, using the Holtzknecht scale. In the case of weak patients a smaller dose is given. The rays are filtered through 1 mm. of aluminium. I obtain this dose during five minutes at 1 ma. and 5–7 a. with X rays whose hardness is 8 on Benoist's radiochromometer and 10 on Wehnelt's criptometer (but the hardness of the rays and duration of radiation are varied in relation to the gravity of the case), and with the anticathode at a distance of 25 cm. from the body. The spleen of monkeys and guinea-pigs is radiated with a somewhat smaller dose and with softer X rays, so that the rontgenisation lasts usually for about ten minutes. The dose and the duration of the rontgenisation is fixed separately for each species of animal, according to the extent of the leucocytolysis occurring in the blood. As the liver and the spleen secrete antagonistic ferments it is very important that the Rontgen rays should not fall on the liver while radiating the spleen. Therefore, for instance, in the case of humans, the radiation of the spleen is done exclusively from the front or back, but never from the side; and, to avoid radiating the liver, when the spleen is being radiating from in front, the right boundary of the tube (8 cm. diameter), which does not let the X rays pass through its sides, must be to the left of the left mammary line, and during rontgenisation from the back it must be to the left of the left scapular line.

Experiments on Animals.

The results of the rontgenisation of the spleen of monkeys and guinea-pigs have proved that leucocytolysis plays an important rôle in the cure of infectious disease.[2] In order to formulate a theory of the significance of the leucocytolysis in the cure of infectious disease I carried out other experiments in Professor Metchnikoff's laboratory, and afterwards in Russia. It appears that rontgenisation of the spleen increases the proportion of alexin and the following specific anti-substances in the blood: hæmolysins, agglutinins, bacteriolysins, and opsonins.[3]

Again, working with Professor Besredka in Metchnikoff's laboratory on guinea-pigs inoculated with human tuberculosis, I tested the blood by the Bordet-Gengou reaction with the tuberculin of Besredka, and at the same time investigated the leucocytolytic properties of the blood. I convinced myself that the curve of fluctuation of specific anti-substances in the blood, revealed by the Bordet-Gengou reaction, was in full correspondence with the curve of fluctuation of the leucocytolysins in it.[4]

Applications of Knowledge Gained by Animal Experiments.

The results of these experiments on animals gave a perfect ground for passing to the application of the method of rontgenisation of the spleen of men for curative purposes.

Pulmonary tuberculosis.—I made my first observations in 1913 on patients suffering from tuberculosis of the lungs in Professor Vaquez's department in the St. Antoine Hospital, Paris.[5] Since that time during seven years I have evolved the application of my method of treatment, not only to tuberculosis, but to a series of infectious diseases.

Typhoid.—During the war, being at the head of a Red Cross hospital for infectious diseases in Kiev, I first tested the curative rôle of rontgenisation of the spleen in cases of typhoid. In the war-time setting the disease gave a very high mortality, being complicated in 40 per cent. of the cases by pneumonia, and it often took a septic course caused by various micro-organisms. Rontgenisation of the spleen reduced the mortality from typhoid to half. But as this method could only enable the organism to combat the bacteriæmia of the blood I attempted to increase the effect by introducing various anti-substances, which reached the blood as a result of rontgenisation of the spleen, into the affected sections of the intestines and their content. With this purpose I supplemented the rontgenisation of the spleen with the feeding of the patients with an autoserum obtained from their blood taken from them 8–10 minutes after the rontgenisation. The autoserum was administered in gelatin capsules. By this means I succeeded in reducing the mortality from typhoid 7½ times. Out of 225 patients not treated by my method 43 died—i.e., the mortality was 19·1 per cent. Out of 351 patients treated by radiation of the spleen alone 34 died—i.e., the mortality was 9·7 per cent. Out of 305 patients treated by radiation of the spleen and by feeding on the autoserum 8 died—i.e., the mortality was reduced to 2·6 per cent.

Tetanus.—After this our hospital had to extend wide medical help to patients suffering from tetanus. The majority were of short incubation period (mostly 5–8 days), which, even with a serum treatment, gave a mortality of 92–98 per cent. After some preliminary tests I established the following treatment for tetanus cases: to each patient, three times a day, 20 c.cm. of serum (prepared by Parke, Davis and Co., or by the Copenhagen Institute, or by ourselves at the Kiev Bacteriological Institute) was introduced under the skin, and 10 c.cm. of one of the above sera was injected intrathecally, together with 10 c.cm. of autoserum obtained from blood taken from the patient 8–10 minutes after rontgenisation of the spleen. Under this treatment the following figures, which are exceptional for war-time, were obtained: of 132 patients 36 died—i.e., the mortality was only 27·3 per cent. and the percentage of recovery 72·7 per cent.

It should be noted that in this case the rontgenisation of the spleen, besides immunising the body to the toxin of tetanus, removed the effect of the serum anaphylaxis. I had already proved in Metchnikoff's laboratory that in the origin of anaphylaxis the anti-leucocytolysins of the liver play an important part; and these, under rontgenisation of the spleen will be neutralised by the leucocytolysins.

Preparation of Curative Sera.

I also availed myself very widely of the rontgenisation of the spleen for the preparation of curative sera. Alongside with the immunisation of horses against the toxin of tetanus (and later also in cases of immunisation of horses against *B. typhosus*, *B. dysenteriæ*, and *Vibrio choleræ asiaticæ*) a rontgenisation of their spleen was performed. Thus I obtained curative sera of high concentration in a shorter time, and was able more readily to meet the great demand for them during war-time and considerably to cheapen the cost. For instance, I prepared the antitetanus serum, containing 2000 American units in 10 c.cm.—i.e., equal to the serum of Parke, Davis and Co. supplied to us at that time, ready for distribution in ampoules in three months.

Other infectious diseases.—I shall not dwell on such acute infectious diseases as acute bronchitis, pneumonia, pleurisy, typhus recurrens, the special "Carpathian" typhus, acute arthritic rheumatism, and acute malaria. They progress very satisfactorily under the influence of one rontgenisation of the spleen of the patients. As to the membranous inflammation of the lungs, I showed that favourable results were obtained by rontgenisation of the spleen before the war in the Maryinsky hospital for the poor in Petrograd.

Dysentery.—In the case of dysentery, which, in our hospital was more often of the Flexner type, and rarely of the Shiga-Kruse type, the progress of the disease was especially favourably influenced by introductions of autoserum, taken 5–10 minutes after radiation of the spleen, into the large intestine through a long syringe.

Non-infectious diseases.—Of non-infectious diseases the following are successfully treated by rontgenisation of the spleen: Bronchial asthma, owing to the connexion between anaphylaxis, which forms the basis of asthma, and the anti-leucocytolysins of the liver, referred to above; hepatitis and cholangitis, since in their case the irritation of the liver is also accompanied by an accumulation of anti-leucocytolysins in the blood; and hæmophilia.[6]

Treatment of Tuberculosis.

I have published in various places in Russia details of the treatment of infectious and non-infectious diseases by rontgenisation of the spleen, and shall conclude this brief exposition by an account of the cure of tuberculosis of various organs.

[5] Published in La Semaine Médicale, May 21st, 1913.

[6] A communication by the writer on this subject appeared in La Semaine Médicale, May 21st, 1913.

Pulmonary tuberculosis.—For the last seven years I have personally treated 8000 cases of tuberculosis, mostly of the lungs, in Russia. I purposely treated them in the most unfavourable climatic conditions—in Petrograd—so that there should be no doubt that the climate played no part in the cure. I only demanded from my patients increased nourishment, so that there should be no lack of building material for the production of leucocytes and various specific anti-substances (whose formation was greatly accelerated by the rontgenisation), and rest during the day of rontgenisation, asking them to remain in bed until 12 A.M. on the day following if possible. During the last two years my patients could not keep even these conditions; they had to be employed to obtain food, and spent much energy in walking to get their very insufficient ration and in doing all sorts of unwonted work. Owing to this the treatment was protracted, but nevertheless even under these circumstances I obtained results which fully justified the method.

In tuberculosis of the lungs radiation is performed not oftener than once a week, and in cases of tuberculosis of the kidneys, bladder, sexual organs, lymphatic glands, or bones once in five days. In Petrograd the treatment of tuberculosis of the lungs of the first stage requires 8–10 seances, of the second stage 12–15, and of the third stage two series of 12–15 each, with an interval between of two or three months. In general I never give more than 15 seances at one stretch.

When the first stage of tuberculosis is treated in this way the temperature (which often rises a trifle after the first seances) falls to normal, coughing decreases, and the patient rapidly gains weight. Of the objective signs the harsh breath-sounds disappear, and the bronchial glands, which are usually swollen, are reduced. When the second stage is treated at first the disease becomes slightly worse. After this the details of recovery vary in different patients, but in the majority of cases, during the second half of the treatment the tubercle bacilli in the sputum decrease and finally disappear. The hæmorrhages cease, if there have been any, the sweats cease, and the patient gradually gains weight. The objective signs become worse at the beginning of the treatment; moist râles appear in abundance in the affected regions, and in places where auscultation has not revealed them before, and the only evidence of disease has been that revealed by X ray examination. After this the moist râles gradually decrease and completely disappear, giving place to symptoms of the ensuing cicatrisation of the tuberculous process.

The third stage responds to treatment like the second stage; its treatment is prolonged according to the size of the cavities present. Radiograms of the lungs taken before and after the seances have plainly showed their cicatrisation towards the end of the treatment. Thus the actual affection of the lungs with the tuberculous process is not in itself a contra-indication of the treatment by rontgenisation of the spleen. This treatment is only inapplicable in cases of extreme exhaustion, accompanied by a vigorous intoxicative affection of the blood-forming apparatus. Again, the treatment is unfavourably influenced by any change of the spleen pulp, for obvious reasons; for instance, patients who suffered from a lingering chronic malaria, with a large and firm spleen, do not react at all to the treatment.

Tuberculosis of kidneys and bladder.—Tuberculosis of the kidneys and bladder usually progresses very satisfactorily under the influence of only 15 seances of rontgenisation of the spleen. At first the tubercle bacilli and blood disappear from the urine, then the temperature, which had risen at the beginning of the treatment as in tuberculosis of the lungs, falls; the pains cease, and finally the urine is gradually cleared of leucocytes.

Tuberculosis of lymphatic glands.—Tuberculosis of the lymphatic glands is also quite successfully treated, usually in 15 seances. In cases where the tuberculous lymphadenitis has led to suppuration of the gland, the abscess is opened surgically, the suppurative secretion gradually diminishes, the infiltration disappears, and the fistula rapidly closes over with a soft cicatrice.

Tuberculosis of bones.—Tuberculosis of the bones also requires about 15 seances. In cases with fistulas the secretion at first increases, then, after 5–7 seances it gradually begins to diminish, the infiltration disappears, the pains cease, and the fistula closes over.

Tuberculous peritonitis.—This condition forms no exception in the general successful progress of this treatment of tuberculous processes.

Tuberculous meningitis.—Only acute tuberculous meningitis does not yield to this treatment. In one case I tried to supplement the treatment by intrathecal injections of autoserum from the blood of the patient, taken after rontgenisation of the spleen. But the injections were made too late. Perhaps, as in tetanus, the application of autoserum from the very first days of the disease will make even these cases yield to treatment.

In better climatic conditions the treatment of tuberculous patients progresses still quicker than in Petrograd. Thus, I had to treat two cases of tuberculosis of the lungs in Naples; the patients lived in Sorrento. The second stage was over after four seances; the first after two. The successful application of the method of treatment proposed by me to various forms of infectious diseases shows that its theoretical foundation is correct. Indeed, the constancy of the results of the application of rontgenisation of the spleen to different infections can only be explained on the theory that it brings in nothing new, but only strengthens the defensive mechanisms organised by Nature.

"It is in this way," as I said in one of my previous articles,[7] "that the organism can avail itself most extensively of the substances present in the leucocytes, for not only do we vigorously destroy the latter, but we also, through this destruction, stimulate the blood-forming organs to an increased production of new leucocytes which will go on breaking up in the blood," saturating the blood-plasm with specific anti-substances which are necessary for the struggle with bacteria and their poisons.

Even from this very concise exposition of the large supply of material at my disposal I think one may convince oneself that, in leucocytolysis, produced by radiating the spleen with a stimulating dose of Rontgen rays, we have acquired a sure method of governing the blood reaction of the organism. We can, therefore, at any moment give radical help to man struggling with various infections.

NOTES OF A
TYPHOID CARRIER CASE.*

BY J. R. CARVER, M.D., D.P.H. CANTAB.,
SENIOR BACTERIOLOGIST, PUBLIC HEALTH LABORATORY,
UNIVERSITY OF MANCHESTER.

THE death occurred in 1914 of a woman who had long been known as a typhoid carrier and to have infected at least 10 persons who lodged with her. The case has been mentioned frequently by Dr. J. Niven, M.O.H., Manchester, in his annual reports to the Manchester Health Committee. A short record of her history may be of interest, as the case had been under observation for several years, and many samples of the excreta had been examined at the Public Health Laboratory of the University of Manchester. Moreover, the woman was under treatment for several weeks at Monsall Fever Hospital, and was again admitted there before her death from malignant disease of the stomach and pancreas, and Dr. Fletcher was able to make a post-mortem examination.

In the autumn of 1907 the attention of Dr. Niven was drawn to the connexion of Mrs. W. with cases of typhoid fever. Inspector Hewitt was instructed to inquire closely into her history, and he presented a report, of which the following is a summary:—

"Mrs. W., aged 54, had good health till 1895, when she had an illness said to be influenza, with headache, pains in back and limbs, delirium, and great sickness. She was for five weeks in a union hospital. Her health after this was good till 1898, since when she has had periodic attacks of great abdominal pain, with vomiting and blood-coloured urine."

---

[7] La Semaine Médicale, 1913, p. 241.

* This report was prepared in the autumn of 1914, but on account of the war was not published.

Cases of typhoid continued to occur in Mrs. W.'s house, and there was barely a year without an infection. Her husband died in 1906, aged 64. He is stated to have had sickness and diarrhœa and an abscess on the side, but it was evidently not considered typhoid. In 1912 she was treated at home with salol and urotropin with a view to free the excreta from the typhoid bacillus, but without success. In January, 1913, she was admitted to Monsall Fever Hospital and treated with an autogenous typhoid vaccine prepared at the Public Health Laboratory. After several weeks' treatment examination of excreta at the hospital gave negative results, and she was discharged April, 1913. One month later the typhoid bacillus was again present in the fæces, but not in the urine, and another case of typhoid occurred in her house the same year.

The Manchester Health Committee then resolved to give her a pension on condition that she took no more lodgers. She began about this time to show signs of malignant disease, and died in Monsall Fever Hospital, May, 1914. The blood was tested on two occasions at the Public Health Laboratory for the Widal reaction; in November, 1907, it was negative, but a year later it was positive, and when patient was in Monsall Hospital, 1913, it was positive.

Table I. shows cases of typhoid which occurred in Mrs. W.'s house from 1898–1913.

TABLE I.

—* No record of Widal test.
† After Mrs. W.'s return from Monsall Hospital.

For a satisfactory examination of the fæces for presence of the typhoid bacillus, &c., it is advisable to give the patient a sufficient amount of sulphate of soda to secure a good fluid evacuation. This is more likely to clear the upper part of the bowel, where the typhoid bacillus exists in greater numbers, and thus renders its detection easier. This method was introduced by Professor S. Delépine many years ago. On arrival at the laboratory successive dilutions are made of the fluid stool and surface cultures are made on litmus lactose agar culture set in Petri capsules. Sometimes the bacillus is found at once in large numbers, but if it cannot be found at the first attempt it is advisable to make several plates from the most suitable dilution. The small blue colonies (non-lactose fermenting) are picked out, subcultured and tested. The urine is centrifugalised and the sediment treated in the same way.

Post-Mortem Bacteriological Examination.

After Mrs. W.'s death at Monsall Fever Hospital, the spleen, liver, kidneys, and mesenteric glands were sent to the Public Health Laboratory for bacteriological examination. Cultures made from the liver, spleen, kidneys, and glands showed a large growth of the *B. coli* only, but it should be remarked that the organs arrived 48 hours after death. In the gall-bladder there was a fair-sized gall-stone of cylindrical shape; this was cut in half and cultures made from the interior. Numerous colonies of the typhoid bacillus was found, as well as a bacillus of the Gaertner group. The typhoid bacillus was also recovered from the bile, but with some difficulty, as it appeared to be growing in symbiosis with a Gaertner bacillus; one distinct colony contained both bacilli.

TABLE II.—*Summary of Examinations of Mrs. W.'s Excreta at the Public Health Laboratory.*

Date.	Specimen.	Result.	Remarks.
Nov. 12th, 1908.	Fæces.	+	Nearly pure growth.
	Urine.	+	—
Dec. 3rd, 1908.	Fæces.	+	—
	Urine.	—	Very scanty growth.
	,,	—	No growth.
Jan. 25th, 1909.	Fæces.	+	In very small numbers.
	Urine.	+	
April 4th, 1912.	Fæces.	+	Nearly pure growth.
	Urine.	+	Very numerous colonies.
Jan. 18th, 1913.	Fæces.	+	Nearly pure growth.
	Urine.	+	do. (vaccine prepared).
May 1st, 1913.	Fæces.	+	Found after repeated examination.
	Urine.	—	Bacillus resembling typhoid, but with no specific agglutination.
May 23rd, 1913.	Fæces.	+	Numerous.
	Urine.	—	—
April 3rd, 1914.	Fæces.	+	Numerous.
	Urine.	+	

Between Jan. 18th and May 1st, 1913, patient was in Monsall Hospital.

Some Further Notes from Various Sources.

A number of specimens of clothing, &c., were collected from Mrs. W., and were examined at the Public Health Laboratory by Dr. Sheila M. Ross, who has kindly given me permission to publish the results. The specimens were: washing from hands; scraping of nails; saliva; clothing—apron, blouse, chemise, drawers. No typhoid bacilli were obtained from any of these, though a bacillus was obtained from the underclothing which in some respects resembled the typhoid bacillus. The *B. coli* was obtained from the underclothing.

Dr. Barbara Cunningham (then assistant M.O.H. for Manchester) has kindly given me some further notes on the case. She says:—

> "Mrs. W. was a woman of clean and refined habits. She was distressed at being considered a source of infection, and gave us every assistance in the investigations. She was never found wearing soiled linen. She was usually constipated, and had periodic recourse to salts to secure an evacuation of the bowel. When at stool she was, owing to her rheumatism, unable to use sanitary paper, but made use of long strips of linen."

Notes from Monsall Hospital.—Dr. Fletcher, at that time medical superintendent, has kindly sent some notes on the case.

Mrs. W. was admitted to Monsall Hospital, Feb. 8th, 1913. The general condition was good and the spleen not palpable. The Widal reaction was positive; the typhoid bacillus was found in fæces and urine from Feb. 14th to April 2nd. An autogenous vaccine was given. The first dose was 100 millions, and it was gradually increased to 1000 millions; there was little or no reaction after inoculations. The only medicinal treatment adopted was helmitol gr. 10 t.d.s. from March 14th to April 12th.

After the beginning of the vaccine treatment bacteriological examination of the fæces and urine were made at the hospital with the following results:—

Date.	Fæces.	Urine.
March 3rd	—	+
April 1st	—	+
,, 3rd	—	—
,, 12th	—	—
,, 27th	—	—

The patient was discharged April 27th, 1913. On May 18th, 1914, the patient was readmitted in a very emaciated condition, with a history of hæmatemesis and incontinence of fæces and urine. She became rapidly worse and died on May 26th, 1914.

Post mortem.—A columnar-celled carcinoma was found involving the pancreas and cardiac end of stomach, with secondary deposits in mesenteric glands. The gall-bladder contained several calculi. On bacteriological examination the typhoid bacillus was found in the gall-bladder but not in the spleen.

Remarks.

Mrs. W. may be regarded as a typical example of a chronic carrier, as opposed to the temporary case, where the bacilli persist for a limited period only after the disease. It is not clear whether the bacilli were present continuously or intermittently. Though they were always found in the examinations here during a period of six years, yet the specimens were mainly sent after the infecting of the various lodgers.

One point of interest is the clear connexion of the gall-bladder with the condition: there were numerous attacks of cholecystitis and biliary colic, and it is possible that these attacks caused a fresh discharge of bacilli into the intestine, then at the post-mortem examination gall-stones were present and the typhoid bacillus was obtained from the bile and from the interior of a gall-stone. Typhoid bacilli were found in the bile as long ago as 1888; and in 1899 Droba was the first to isolate them from the interior of a gall-stone. Some years ago I examined a number of gall-stones in association with Dr. E. M. Brockbank, and in almost every instance a bacillus of the Gaertner group was obtained from the interior, usually in pure culture. It is probable that some bacterium is always the centre of the crystallisation of the gall-stone.

Dr. Fletcher makes no mention of any ulceration of the intestine, so we may accept the gall-bladder as the source of the bacilli found in the fæces; but what of their presence in the urine? Ledingham, in a long report to the Local Government Board,[2] states that in chronic typhoid carriers he never finds the bacilli in the urine of a male, and only occasionally in the female, and he believes it is always due to external contamination and is not found in a catheter specimen.

In the above recorded examination, while the bacillus was always present in the stools, it was found in the urine in 55 per cent. of specimens. In Monsall Hospital the bacillus was found in the urine on two occasions when it was not found in the fæces. My view is that although it may reach the bladder by external contamination it multiplies there, and is frequently present in enormous numbers. During the vaccine treatment, it appeared to persist longer in the urine than in the fæces. It will be noticed that the patient underwent treatment by various drugs, and had a full course of vaccine treatment at Monsall Hospital, an autogenous vaccine being used. The vaccine treatment appeared to be of temporary benefit, but within two months of leaving the hospital she had infected another lodger, and the bacillus was isolated from the fæces. Ledingham[1] states that the only permanent cures on record have been due to surgical treatment of the gall-bladder.

In this case the Widal reaction was negative at one time, but on two other occasions it was positive. Ledingham[1] finds in the numerous cases he has collected that the reaction was positive in about 70 per cent., but there is little evidence as to variation of the reaction.

As to the public health aspect of the case, it is evident there should be some compulsory powers to prevent a typhoid carrier from taking up any occupation in regard to preparing or serving food or drink of any kind.

My thanks are due to Professor Delépine for kind advice; to Dr. Niven and Dr. Cunningham, of the Manchester Health Office; Dr. Fletcher, of Monsall Hospital; and Dr. Ross, of this laboratory, for their kindness in permitting me to make use of their reports and notes.

---

[2] L.G.B. Reports, 1908-9.

WELSH NATIONAL MEMORIAL.—The quarterly meetings of the National Memorial (Tuberculosis) Association, held at Shrewsbury on March 18th and 19th, were of unusual interest, in that the newly appointed chief medical officer, Professor Lyle Cummins, met the committees for the first time. The future medical work of the association, which controls over 1000 beds in 18 institutions, in addition to tuberculosis dispensaries, was carefully considered and planned, and the way in which it will be coördinated with organised research set on foot by the Medical Research Council was explained. Both the medical staff and the medical committee felt that the future of the work had better prospects ahead than has been the case since the war interfered with progress. Various appointments were announced, including that of Sir Robert Philip as honorary consulting physician, Mr. W. Thelwall Thomas as consulting surgeon, and Sir Henry Gauvain and Major Alwyn Smith as consulting physicians.

VASCULAR CHANGE DURING UTERINE INVOLUTION:

A STUDY OF THE CONDITION OF THE ARTERIES IN A UTERUS REMOVED 24 DAYS AFTER DELIVERY.[1]

BY GEOFFREY EVANS, M.D. CANTAB.,
M.R.C.P. LOND.,
ASSISTANT DIRECTOR OF THE MEDICAL PROFESSORIAL UNIT AT, AND ASSISTANT PHYSICIAN, ST. BARTHOLOMEW'S HOSPITAL.

DURING the past 70 years many observers have made a close study of the histological changes that occur in the uterine vessels in the course of normal involution of the uterus after labour. It would seem that after so much inquiry there can hardly be any aspect of the subject in dispute or new observation to be made. In recent years a very complete research into this subject has been carried out by Dr. James Goodall, and both on account of its intrinsic merit and the fact of its being quoted at length in Eden and Lockyer's "New System of Gynæcology" it may be accepted as the standard work on the vascular changes that take place in uterine involution. The present communication deals with a single aspect of this subject—namely, the presence or absence of fatty degeneration in the muscle fibres of the arteries of the uterus undergoing involution.

The majority of past observers have found that fatty degeneration does occur both in the muscle fibres of the uterus and the muscle fibres of its vessels. In fact, there is no need to make any distinction in dealing with this subject between the muscle fibres in the two tissues, because there is no record of fatty degeneration occurring in the one group of muscle fibres while absent at the same time in the other group; the converse also holds good. Some have noted the appearance of fatty degeneration at an earlier stage in the puerperium than have others, but there has been little difference of opinion as to the fact of its occurrence. Goodall agrees with the majority of past observers and notes the presence of fatty degeneration in the muscle fibres of the uterus and arteries of the uterus, and states that "the muscle cells of the parent media undergo fatty degeneration at an early stage in the process of involution."

Description of the Case.

Dr. H. Williamson has kindly given me the opportunity of preparing specimens from a uterus removed at operation 24 days after delivery of a dead fœtus.

The case was that of a patient, aged 41, admitted to St. Bartholomew's Hospital under Dr. Williamson on Sept. 6th, 1919, on account of bleeding from the uterus and 25 weeks gravid. She was found to have a carcinoma of the cervix which extended up to, but did not involve, the posterior vaginal wall. The patient had had eight children, with straightforward labours and no miscarriages. The menstrual history was normal. The present pregnancy was normal until the onset of bleeding in April. On Sept. 17th, under general anæsthesia, the membranes were ruptured and abortion induced. At 2 A.M. on the 20th—that is, in the twenty-seventh week of the pregnancy—abortion took place. The fœtus was born dead, but not macerated. On Oct. 14th, 24 days after the delivery of the dead fœtus, Wertheim's hysterectomy was performed and the uterus removed.

The organ was placed in formol-saline, and at a later date parts of it were removed for section. The separate parts were embedded in gelatin according to Dr. J. F. Gaskell's method and cut frozen. Sections were stained in Sudan III. and acid hæmalum, others in Van Gieson and acid hæmalum, and others in Weigert's elastica and eosin. The advantages of the gelatin method of embedding are that the tissue is not raised to a higher temperature than 37° C., and is not brought into contact with xylol; as a result the cells retain their normal form more nearly, and any fat present is not dissolved out of the tissues.

The sections thus prepared show the usual changes in the vessel walls characteristic of normal arterial involution. The most striking changes occur in the intima; there is a cellular proliferation and hyaline swelling of the subendothelial layer, together with a swelling and splitting of the internal elastic lamina. In the media there is the appearance of a granular atrophy of the muscle fibres and a hyaline swelling of the intermuscular connective-tissue fibrils.

---

[1] A paper read at the Section of Obstetrics and Gynæcology of the Royal Society of Medicine on March 3rd, 1921.

Remarks.

The picture has been often described and does not require detailed notice; in fact, the only point to which I would draw attention is the absence of any sign of fatty degeneration either in the medial coats of the vessels or in the muscle fibres of the uterus. The histological picture of the vessels in this specimen are in all respects comparable to the changes seen in the involution of the hypogastric and umbilical vessels after birth. I have examined many specimens of these vessels up to two years after birth and have not observed fatty degeneration occurring in the media in any vessel. Neither does fatty degeneration occur in the involution of arteries after ligature or thrombosis, nor in the normal involution of the ductus arteriosus; in fact, so far as I am aware fatty degeneration is not a normal feature of arterial involution. It would appear that it is only in uterine involution that fatty degeneration occurs in vessels undergoing this physiological change. The absence of fatty degeneration in my specimen is therefore in accord with the general observations on the changes that take place in arterial involution, and it further establishes the fact that fatty degeneration need not of necessity occur in uterine involution.

The presence or absence of fatty degeneration in uterine involution is a matter of importance to a proper understanding of the processes involved in the varied arterial lesions described under the term of "arteriosclerosis." Thus Thoma maintained that slowing of the blood stream was a dominant factor in the production of arteriosclerosis, and he based his theory largely on the change occurring in the iliac and hypogastric arteries of newly born infants. Thoma's theory of arteriosclerosis is chiefly concerned with the process of involution. The weightiest single piece of evidence against this hypothesis is the characteristic presence of fatty degeneration in the histological picture of arteriosclerosis and its absence in normal involution. But this distinction will fail if it is established beyond doubt that fatty degeneration occurs in the media of arteries undergoing involution in the puerperal uterus. I do not feel that it is expanding the subject too far in applying the observations on arterial changes in uterine involution to the wider subject of arteriosclerosis, because Goodall follows his observations to the same goal, and in discussing their bearing on arteriosclerosis he concludes by stating that his work seems to prove that both Jores and Thoma are right in their views as to the nature of the processes underlying the production of arteriosclerosis.

A Critical Examination of Current Views.

It is difficult to dismiss the work of past observers who have found that fatty degeneration always occurs in uterine involution, and at the same time in their writings there is not, in general, sufficient detailed information given to allow of adequate criticism of their material or methods. As regards my own specimen it may be objected at once that the pregnancy had not gone to full term and that the organ was in a condition of subinvolution. This criticism is fair, and one of my objects in bringing this matter forward is the hope that it may lead to my having better material to examine on a future occasion. The criticism, however, loses some force in that fatty degeneration is absent in my specimen: had it been present it might have been ascribed to subinvolution, but subinvolution cannot account for its absence. In the second place the criticism fails to an extent because the material of those who have found fatty degeneration in the muscle fibres of involuting uteri is also abnormal. I have not read any account of arterial changes in human uterine involution which avoid this criticism.

It would take too long to justify this statement in detail, but to illustrate my meaning I will take Dr. Goodall's research. It is based on the examination of 80 uteri, but the observations on the subject of the changes that occur in the puerperal uterus are based on only six cases. Goodall states that five of these showed subinvolution; in the sixth there was a morbid lesion, which one would expect to interfere with the process of normal involution.

It is a mistake to regard Goodall's observations as a record of the changes that occur in normal uterine involution, for he states on p. 61 of his monograph that "all the chronic inflammatory diseases, blood dyscrasias, ... and possibly malignant growths modify the normal complete involution." As there is no doubt as to the truth of this statement it is fair to assume that any unexpected histological features presented by uteri taken from cases in which any of these conditions were present are capable of explanation in terms of a pathological process rather than in terms of the physiological process involution. Further, in the six cases on which Goodall based his observations the cause of death was in all cases due to a disease which might in itself have caused both vascular disease and fatty degeneration in muscle fibres. Thus Case 1 died of "eclampsia, associated with, or caused by, a very grave chronic parenchymatous nephritis." Case 2 died of "syphilitic arteritis of the brain." Case 3 died of "septicæmia, secondary to an abscess of the breast with subinvolution." Cases 4 and 5 died of tuberculosis of the lungs, while Case 6 died of "acute yellow atrophy of the liver, chronic parenchymatous nephritis, and broncho-phthisis incipiens." An interesting comment is made on this case, for the author writes: "Hence it is seen why Case 6, who had had chronic Bright's disease, followed by acute yellow atrophy of the liver, should present such intense degree of incomplete oxidation of tissue," and in another paragraph that "such cases must be looked upon as abnormal." It is obvious that the author recognised his material as being pathological, and he cannot be blamed for his work being mistaken for an account of the changes that occur in normal involution. When a condition of suboxidation exists fatty degeneration may be expected to occur, and therefore before it is established that fatty degeneration is a part of the normal process of uterine involution it must be found to occur in a uterus taken from a healthy subject. Further, as regards the presence of fatty degeneration in the media of the vessels, it must be proved that the other vessels in the body are normal in order to exclude the possibility of the local vascular fatty degeneration being part of a diffuse vascular disease. This last condition will be fulfilled, in my opinion, if the intimate vasculature of the spleen and kidney are found to be normal, because I have found that diffuse vascular disease tends to have its chief incidence on these two organs.

Conclusion.

It must necessarily be difficult to obtain material from the human subject which will satisfy these conditions, and in the meantime we must rely on observations made on uterine involution as it occurs in animals.

Such observations have been made on rabbits.

Broers found that fatty degeneration occurred in the muscle fibres of the uterus between the third and thirtieth day of the puerperium; no reference was made to its presence or absence in the media of the vessels. Helme made similar observations on 10 rabbits, and since his work was primarily directed to this question it is of particular importance. He thus states the object of his research: "The prime question that presents itself is: Does a degeneration of muscle cells occur?" His answer is: "I have been unable to find a single muscle cell whose substance gave the characteristic appearances and reactions of fat," and later he speaks of the occurrence of a gradual diminution of the volume of the muscle cells of the media, "just as in the muscle cells of the uterine wall."

Too close a parallel cannot be drawn between the changes that occur in uterine involution in animals and those that occur in the human subject. There is also a conflict of observation. I think, however, that the conclusion is justified that the question of the presence or absence of fatty degeneration in the media of the vessels in the puerperal uterus is not as yet definitely settled.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

TWO CASES OF PERINEPHRIC ABSCESS.

BY OCTAVIA WILBERFORCE, M.R.C.S., L.R.C.P. LOND.,
HOUSE PHYSICIAN, ST. MARY'S HOSPITAL, PADDINGTON.

With a Note by

WILFRED HARRIS, M.D. CANTAB., F.R.C.P. LOND.,
SENIOR PHYSICIAN, ST. MARY'S HOSPITAL.

THE following two cases of perinephric abscess, admitted under the care of Dr. Wilfred Harris (to whose courtesy I am indebted for permission to publish these notes) at St. Mary's Hospital, Paddington, and operated on within 24 hours of each other, present certain features of interest:—

CASE 1.—A. M., male, aged 41, admitted Jan. 8th. Sent by a doctor who wrote that he had first seen patient on Dec. 14th, 1920. At that time patient complained of great pain in left lumbar region radiating forwards towards the left groin. Temp. 103° F. This condition continued on and off till Dec. 28th, when pain shifted upwards over base of left lung, where signs of pleurisy were noticed, and on Jan. 4th on exploration, a hæmorrhagic fluid was withdrawn. On the 6th a painful tender swelling appeared in the left lumbar region. Temp. 101°. Family history of T.B. On admission a further history was elicited of a boil in the neck which began during the last week in November, 1920. This was incised and drained, and as it cleared up early in December the patient first noticed a gnawing pain in left lumbar region which gradually became acute; on Dec. 14th he took to his bed.

Condition on admission.—Patient appeared wasted, toxic, and very weak; T. 102·4°, P. 120, R. 26, and very shallow. Signs of pleural effusion over left side reaching to axilla. The urine contained no pus or blood, and only a slight trace of albumin. A diagnosis of perinephric abscess with accompanying pleural effusion was made, and on Jan. 9th Mr. C. W. G. Bryan operated under local anæsthesia (novocaine), the patient's condition not warranting a general anæsthetic. He first removed by aspiration about 2 pints of hæmorrhagic fluid from the pleura, and then making an incision over the site of the abscess evacuated about 1½ pints of pus. A drainage-tube was inserted for four days, when the wound was allowed to heal. Temp. dropped to normal, and patient made an uninterrupted recovery with no further chest symptoms.

Pathological report.—(1) Pus: Direct film, many Gram-positive cocci, polymorphs and lymphocytes. Cultures: Many staphylococcus colonies. (2) Pleuritic fluid: Many cells, lymphocytes rather more numerous than polymorphs, no organisms seen. Cultures; No organisms grown. No T.B. found in either specimen.

CASE 2.—T. H., male, aged 50. Admitted Nov. 20th, 1920, for "gastritis" and wasting. He gave a history of boils in the anal region recurring from May till the end of August, 1920, when he had "influenza" with much vomiting followed by pneumonia and "gastritis." He was confined to bed, became much thinner, and continued to run a temperature until his admission to hospital. On admission he was obviously much wasted, seemed listless, T. 99·8°, P. 120, R. 26. Heart not enlarged, no murmurs audible. Other systems normal. Patient very constipated, carious teeth and pyorrhœa present. On Nov. 27th cultures of *Staphylococcus albus* were grown both from blood and urine. A blood count (Nov. 29th) showed: r.b.c., 4,000,000; Hb, 54 per cent.; colour index, 0·6; w.b.c., 24,000; polymorphs, 64 per cent.; small lymphocytes, 32·5 per cent.; large lymphocytes, 2·5 per cent.; large hyalines, 1 per cent.

The patient was treated with an autogenous vaccine without benefit, nor did improvement result from extraction of all his teeth. Temperature was of a septic type, fluctuating between 97·5° and 102·4°. Pulse-rate 100 to 120. Constipation remained obstinate from admission until Dec. 22nd, when an attack of diarrhœa supervened, lasting eight days. On Jan. 10th, for the first time, a small, fluctuant, painless swelling the size of a Tangerine orange was noticed in the right lumbar region about four inches to the right of the spine. This was only slightly tender on deep palpation. A blood count now showed: r.b.c., 4,000,000; Hb, 38 per cent.; colour index, 0·45; w.b.c., 16,000; polymorphs, 79 per cent.; small lymphocytes, 17 per cent.; large lymphocytes, 1 per cent.; large hyalines, 3 per cent. A perinephric abscess was diagnosed. The patient was operated on by Mr. C. A. Pannett and about a pint of pus evacuated. Temp. dropped to normal, drainage-tube was removed on the twelfth day, and patient was discharged from hospital Feb. 3rd.

Pathological report.—The pus removed from the perinephric abscess contained polynuclear cells and masses of Gram-positive cocci, presumably staphylococci. Cultures on blood-agar plates gave pure culture of a *Staphylococcus albus*.

Note by DR. WILFRED HARRIS.

The coincidence of two cases with perinephric abscesses, secondary to boils, being met with so close together is unusual. Case 1 was admitted and operated on as an urgency after my house physician had made the diagnosis of perinephric abscess without my having seen it. Case 2 had been a puzzle to us for weeks. The patient was evidently suffering from septicæmia, and gave a blood culture of *Staphylococcus albus*, but I had examined the patient carefully for signs of suppuration on more than one occasion, nothing more blameworthy than pyorrhœa and carious teeth being found. Ulcerative endocarditis was considered as a possible explanation, though no bruit ever appeared. The man gradually wasted and weakened, and undoubtedly would have died had it not been that Miss Wilberforce in this case also discovered a swelling over the right loin.

A NOTE ON
HERPES ZOSTER AND VARICELLA.

BY JAMES WATT, M.A., M.D. ABERD., D.P.H.,
MEDICAL SUPERINTENDENT, THE DOWNS SANATORIUM, SUTTON.

IN view of the controversy regarding the ætiological connexion of herpes zoster and chicken-pox, every case likely to afford any evidence of value ought to be reported.

P. R. M., male, aged 39, was admitted to the Downs Sanatorium on July 12th suffering from pulmonary tuberculosis, affecting both lungs, mainly the left, and complicated with chronic bronchitis. Tubercle bacilli were present in sputum. Temperature was normal till the 26th. On that and the two following days the morning temperature rose to 98·0° and 98·2° F., and evening to 99·2° and 99·4°. On July 29th, 30th, and 31st the level rose to 98·6° to 99° in the morning and 99·4° to 100·2° in the evening. Pulse-rate ranged between 80 and 92. On the 25th and following days patient complained of severe pain in left side and back, and on the 29th a typical herpes zoster appeared on the left side, the eruption being confluent and covering the left scapula below its spine, extending half an inch beyond its inner border. The following day another group of vesicles covering an area as large as a penny appeared in the middle of the left axilla, and a third area extended from outside the left nipple along the fourth and fifth interspaces below it. On August 1st a papular eruption appeared with the distribution of a small-pox rash, and the evening temperature rose to 101·4° F. The papules were profuse on the forehead and the rest of the face, scattered on the trunk, and sparse on the upper and lower limbs. On the 2nd many were vesicular and of diverse shape and size. Chicken-pox was diagnosed, and confirmed by Dr. W. Habgood, medical officer of health for Sutton, and later by Dr. F. M. Turner, of the South-Eastern Fever Hospital, to which the patient was transferred on August 2nd.

The sequel, however, raised a doubt. Dr. Turner has kindly sent the following further notes:—

On admission this man had obvious herpes zoster. The lesions were of very unusual size, but otherwise typical. In addition to the herpes lesions he showed numerous small pustules and scabs scattered over face, trunk, and limbs, suggestive of chicken-pox, and of no obvious distribution or arrangement. On August 17th he had a fresh outbreak of herpes along the third and fourth left intercostal spaces, the anterior axillary fold, and down the inner side of the left arm, with severe pain in all these regions. There were some herpetiform spots, also painful, on the right side of the chest between the anterior and posterior axillary lines. On the 20th there were herpetiform lesions over both sides of the chest, a few on the abdomen and on both upper arms. There was still considerable pain. Temperature did not exceed 99° F. Gradual subsidence then followed. In view of the distribution of the second rash, which at first simulated herpes zoster, but later was anomalous both for herpes and for chicken-pox, and in view of the rarity of relapse of chicken-pox, I began to doubt the evidence of chicken-pox in the first attack.

This man had been vaccinated in infancy, and when 9 years of age had been sent to hospital for small-pox. As he was sent home again within a fortnight, it probably turned out to be chicken-pox. Neither he nor any of his family had previously had herpes, nor had any of his six children had chicken-pox.

ROYAL MEDICAL BENEVOLENT FUND GUILD: BRISTOL BRANCH.—At a meeting held in the Council Chamber of the University, presided over by the Lord Mayor of Bristol, Mrs. Lauriston Shaw gave an interesting account of the work of the guild, chiefly on behalf of needy dependents of deceased medical men, work which is supplementary to that of the fund itself. She laid particular stress on the valuable assistance to the education of children of medical men, which the guild has been able to furnish, and made a number of suggestions as to methods of collecting funds. The meeting, which was well attended, was also addressed by the Lord Bishop of Bristol, the Master of the Society of Merchant Venturers, and Mrs. Hugh Stack, the secretary of the Bristol branch of the guild, a branch which is the fifth largest in the country, with 112 members.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF MEDICINE.

A MEETING of this section of the Royal Society of Medicine was held on March 22nd, Dr. A. F. VOELCKER, the President, being in the chair.

Dr. F. PARKES WEBER read a paper on

THROMBOSIS OF THE INFERIOR VENA CAVA,

in which he described the case of a patient who had been under his care with this condition plus thrombosis of both renal veins.

The patient was a man, aged 40, who had been admitted to hospital under the care of Dr. M. L. Schroeter in September, 1920. In the spring of 1919 he had suffered from a septic wound of the right hand. This was followed by an attack of thrombo-phlebitis in the left lower extremity, and at the same time a gradually increasing hydrocele on the left side was first observed probably (as was later seen) connected with venous obstruction from thrombo-phlebitis of the left pampiniform plexus. The right testis was undescended but could be palpated as a mass about as big as a large walnut on the right side of the lower front of the abdomen. The man had had gonorrhœa but never syphilis, and his Wassermann reaction had been found to be negative on three occasions. The urine was of rather low specific gravity, and contained a trace of albumin; no sugar. Otherwise nothing special was found on ordinary examination.

The hydrocele was operated upon at the end of the month. About two weeks later thrombo-phlebitis in the right internal saphenous vein was observed and was accompanied by slight pyrexia. Sodium citrate, 15 gr. three times daily, was prescribed and continued for three to four weeks and a diet containing sufficient green vegetables and fruit. The fever lasted about ten days. About a month later the superficial veins on the front of the abdomen were markedly dilated, more especially on the left side, and the circulation in them was from below upwards. There was slight œdema of the lower extremities. After about a fortnight there was thrombo-phlebitis in one of the superficial veins on the left front of the abdomen and a little temporary fever.

Early in December the patient was transferred to the medical side of the hospital under the care of Dr. Weber. For three days he had been passing very little urine. There was no definite ascites, but the abdomen was rather full (? venous engorgement). The daily quantity of urine was 200 c.cm., the specific gravity was 1012, acid, free from sugar, and practically free from albumin. The brachial systolic blood pressure was = 165 mm. Hg. There was considerable pain in the lumbo-sacral region for a week and much headache for a fortnight. For three days there was apparently anuria, which seemed clearly due to thrombotic obstruction in both renal veins. He was given two injections of urea (2 g. and 4·2 g.) subcutaneously on consecutive days and treated by hot hip baths for five days. The amount of urine passed increased gradually, was of low specific gravity, and contained a little albumin. There was occasionally a little vomiting and one short epileptiform attack.

About the middle of December the superficial veins of the collateral venous circulation on the trunk were becoming much more dilated. There was dullness to percussion at the base of the right lung, apparently due to pleural effusion, and afterwards a little dullness at the base of the left lung also. Ophthalmoscopic examination by Dr. C. Markus showed nothing definitely wrong in either fundus. The superficial veins over the back of the trunk became collaterally dilated as well as those on the front. At the present time the patient's condition was much as at the end of January. There had been three transitory epileptiform attacks, evidently not of uræmic origin. He was passing about 1450 c.cm. urine in the six hours, the specific gravity was about 1015, and there was a "cloud" of albumin and a few tube casts. There was still slight dullness at the base of both lungs behind.

In discussing the condition Dr. Weber said that, apart from thrombotic obstruction of the inferior vena cava connected with malignant tumour, thrombo-phlebitis might follow traumatism, some infection—such as typhoid fever, varicella, erysipelas, or, as in this case, a septic wound. In such cases the patient might recover and live for a long time, but not very much was known as to the exact subsequent history and the average duration of life. Sooner or later a special liability probably developed to attacks of thrombo-phlebitis in the enlarged (varicose) veins.

In 1907 he had seen a man, aged 26 years, whose inferior vena cava had become thrombosed seven years previously as a sequel to typhoid fever. The thrombosis was associated with the usual œdema of the legs and compensatory enlargement of superficial veins, which had reached their maximum six weeks after the first signs of thrombosis. Since then the man had had three attacks of thrombosis in the left lower extremity and had had varicose ulcers and pigmentation of the legs. Dr. Weber had heard that his condition in 1912 was much the same as in 1907.

Dr. J. L. Bunch had recorded a case of traumatic thrombosis of the inferior vena cava in a man aged 33, who, three years previously, after exertion in running, suffered from œdema of the legs, and developed collateral enlargement of the superficial veins of the abdomen and groin.[1]

In 1903 Dr. Weber examined an active, fairly muscular, energetic man, aged 28½ years, for life assurance, in whom the superficial veins of the lower extremities and lower part of the trunk were greatly enlarged, doubtless resulting from traumatic thrombosis of the inferior vena cava. About five years previously, after a carriage accident, his lower limbs had become swollen, and the superficial veins of these limbs and of the lower part of the trunk began to enlarge. He had been kept in bed for five months. He was otherwise in good health, and his urine was free from albumin. His life was accepted for a whole-life policy, with 10 years extra, and in 1917 Dr. Weber ascertained that the insurance was still in force and the man was about to pay his last premium.

Dr. Weber then gave a short account of the case of the late Dr. W. Rivers Pollock, who suffered from thrombosis of the inferior vena cava at the age of about 24 years.

The whole history was published by Professor S. G. Shattock, because the patient himself had bequeathed the affected parts of his body for dissection to the Royal College of Surgeons. When the thrombosis occurred (1884) he was in perfect health and won the 120 yards hurdle race for Cambridge University against Oxford in the record time of 16 seconds, holding his breath through the whole race. Immediately after the race was over he lay on the grass, and within a few seconds complained of pain in the lumbar spinal region. He was kept in bed for six months. The œdema of his legs and lower part of the trunk which at once supervened was followed in a few days by progressive enlargement of the superficial veins. Albuminuria, which likewise appeared after the injury, persisted throughout his life. Death occurred 25 years later from tonsillitis and septicæmia. During the last six years of his life he had been subject to attacks of thrombo-phlebitis in the enlarged saphenous veins. Professor Shattock found that the inferior vena cava was converted into a flat impervious ribbon from the point of entry of the hepatic vein downwards; both right and left renal veins were closed at their entrance to the vena cava, so that the return of blood from the kidneys must have taken place through the veins of the capsules and thence by way of the lumbar veins through the azygos vessels. Professor Shattock argued that the thrombosis was probably secondary to the rupture of the inner coat of the vena cava caused by the violent strain of the race with the holding of the breath; he compared the venous condition in question (for which he suggested the name "dissecting varix") to the arterial condition known as "dissecting aneurysm" when, owing to some violent strain or previous disease, a rupture of the inner coat of the aorta had occurred.

The paper was discussed shortly by Sir HUMPHRY ROLLESTON.

A TUBERCULOSIS IMMUNISING VACCINE.

Dr. NATHAN RAW read a paper on this subject. He said that in spite of an enormous amount of research we had not yet obtained a specific remedy which would effectively destroy tubercle bacilli in the body. Therefore we had to rely on producing a sufficient immunity in the tissues to resist the attack of virulent tubercle bacilli. This immunity could be obtained (1) by increasing the natural resistance by means of increased nutrition and sound hygienic conditions, and (2) by producing an artificial active immunity in the tissues. At the annual meeting of the British Medical Association in 1903 he had expressed the opinion[2] that human and bovine tuberculosis were separate and distinct infections, producing a different set of symptoms in the human body. The lesions caused by the human bacillus (direct infection) were pulmonary tuberculosis, tuberculous laryngitis, secondary intestinal ulceration, and, in some cases, lupus. The lesions caused by the bovine bacillus, which were generally caused by infected milk in the early years of life, were tuberculous glands, mesenteric tuberculosis, surgical tuberculosis, bones and joints, &c. (frequently), tuberculous meningitis, and some cases of lupus. Dr. Raw said that not only did he still hold to this classification and differentiation, but he firmly believed that one form of tuberculosis conferred an immunity in the body to the other form—in fact, that the two varieties of bacilli would not exist together in the body at the same time.

After treating over 2000 cases of tuberculosis in hospital with Koch's tuberculins, prepared from virulent cultures, he had come to the conclusion that, although a certain amount of success was obtained, the results were not, on the whole, satisfactory. The uncertain action of the tuberculin and the alarming reactions sometimes produced were very disconcerting, and there was no doubt that in certain cases quiescent tubercle was stirred to acute activity. For this reason he came to the conclusion that it was essential to use cultures of very low virulence and to avoid, if possible, general febrile reactions. The only certain way of permanently attenuating virulent cultures of tubercle bacilli was long-continued and systematic subculturing spread over a number of years. In 1906 Professor Koch had given him a pure culture on glycerine agar of human bacilli from the sputum of an advanced case of pulmonary tuberculosis. Professor Calmette had supplied him with a pure culture of bovine tubercle bacilli from the mesenteric glands of a cow, and Professor Bang, of Copenhagen, a pure culture of avian bacilli from the liver of a chick. These cultures had been subcultured on glycerine potato and then transferred to glycerine agar every month for 14 years in his laboratory, the present growths representing the 184th, generation. The growths were still profuse and true to type, but were quite non-tuberculigenic and non-pathogenic to animals. Every year since 1906 he had injected these bacilli into animals, and until 1912 had noticed no change in their virulence, i.e., to the 94th generation of subcultures. Afterwards attenuation became marked, and by a series of animal inoculations in 1913 and 1914 they were observed to be avirulent. During the war he took the cultures to France and continued the investigation there for four years, inoculating hares, rabbits, and guinea-pigs in 1916 and 1917. The cultures were in all cases non-pathogenic. In 1919 he inoculated more animals at the Lister Institute with large doses, but no infection was conveyed, and the animals remained alive and well for four months. These experiments, extending over 14 years, proved that virulent tubercle bacilli could be attenuated to such a degree as to be avirulent and non-pathogenic to highly susceptible animals, and showed, in his opinion, that we had a remedy against tuberculosis which would be of the greatest value, not only in the cure of the disease but in its prevention. Natural attenuation, while removing the virulence and toxicity of the organism, enhanced the value of the vaccine in treatment. In small-pox the immunity derived from inoculation of the virus of vaccinia was considerably greater than that which resulted from an attack of variola, because the defensive elements of the body had not been weakened in overcoming the virulence of the toxin. The treatment of disease by vaccines prepared from organisms attenuated naturally meant that the production of antibodies would take place rapidly without the preliminary shock which invariably followed the injection of a vaccine prepared from a virulent strain. Hitherto it had not been possible to test this in tuberculosis owing to the length of time necessary to produce a non-pathogenic strain of the bacillus.

---

[1] Proc. R.S.M., Sect. of Path., 1913, vi., p. 126.

THE LANCET, 1903, ii., 473.

His work on animals had shown that immunity against infection was produced by injection of attenuated bacilli; and it was reasonable to suppose that the same would hold good in the human. Cattle could be rendered immune to virulent bovine bacilli by previous inoculation with virulent human bacilli, and he was convinced that there was a marked antagonism in the human body between human and bovine infections; these two organisms could not flourish in the body at the same time. A child who developed a primary abdominal tuberculosis with involvement of the mesenteric glands or an infection of the neck glands, which were usually caused by the bovine bacillus, was immune to the human bacillus, and young adults attacked by the human bacillus, producing primary pulmonary tuberculosis, were similarly immune to bovine infections for the rest of life. The differentiation between human and bovine infections in the body was not sufficiently accurate to be decisive. There were atypical strains of bacilli which could not be classed with certainty, and the varying virulence of these bacilli and their effects on susceptible animals were still a matter of some uncertainty in a fair number of cases. With a view to determining whether the disease caused by the human bacillus was antagonistic to that caused by the bovine bacillus and vice versa, he had instituted a clinical observation on a large scale in a Liverpool hospital of 900 beds, of which he had sole charge for 18 years. During that time he had had the opportunity of treating over 10,400 persons suffering from tuberculosis in all its forms. There were 200 beds for tuberculosis, half for primary pulmonary tuberculosis and half for surgical tuberculosis—glands, bones, joints, and lupus. During this period there were 4800 cases of phthisis and 1820 cases of surgical tuberculosis. In no case of primary pulmonary tuberculosis were any of the following lesions developed during the course of the illness: tuberculosis of bones, glands, skin, or tuberculous meningitis. Several cases developed brain symptoms during the last stages of the disease, but they were due to insanity, toxæmia, or exhaustion, and in cases with meningeal symptoms, those examined post mortem were found to be of pneumococcal meningitis. Amongst the surgical cases 28 developed lung symptoms, and were examined by laboratory methods and animal inoculation. Of these, 25 died and were carefully examined post mortem. In all cases the infection in the lung was either by direct extension from cervical glands to the apex of the lung, or from a primary focus in the abdomen through the diaphragm to the bronchial glands and lungs. This clinical experiment convinced him that the human body was attacked by two quite distinct forms of tuberculosis, one conveyed from person to person by direct infection and attacking chiefly the lungs, or so-called consumption, the other conveyed by milk from tuberculous cows and developed in the first few years of life. These two diseases were caused by different types of tubercle bacilli which would not live in the body at the same time, and one disease produced immunity to the other. For this reason he always used a vaccine prepared from bovine cultures in the treatment of the human infections and vice versa. Most cases of tuberculosis were of low virulence and, given suitable conditions, were favourable for treatment, but in some cases the virulence was so high as to destroy the person in a few weeks or months, and these were the cases popularly known as "galloping" consumption. He thought that the virulence of the tubercle bacillus in this country was less than it was 30 years ago; the number of deaths from tuberculosis in 1920 in England and Wales was 12,000 less than in 1919. A large percentage of the population were immunised to some extent against further and more severe infection by having had a mild infection of tubercle, and if we could induce some immunity by artificial means in children whose parents were tuberculous, and who, by constant association with them, were liable to infection, we should have gone a long way towards stamping out tuberculosis.

The vaccine which he had prepared from these attenuated cultures was a bacillary emulsion of the bacilli, and contained all the products of the bacillus. It was non-toxic and avirulent, and produced no reaction, even in large doses. For purposes of immunisation of susceptible children six injections were given at weekly intervals, and repeated in three months. The doses recommended were 0·001, 0·002, 0·003, 0·004, 0·005, and 0·006 mg. No symptoms whatever had been observed to follow these injections. In the treatment of the active disease the doses used were much larger than had been possible hitherto; and the treatment should consist of at least 12 injections given in increasing doses at intervals of seven days. The doses commenced at 0·0001 and increased to a maximum dose of 0·025 mg. The vaccine should be freshly prepared from the cultures and should not be used after one month. The vaccine could be used with complete safety in any stage of the disease, and even in advanced cases he had observed great relief from night sweats, toxic symptoms, and erratic temperatures. The results in suitable cases were excellent, but it would require at least two years accurately to gauge the effect of the vaccine for purposes of immunisation.

Discussion.

Sir JAMES KINGSTON FOWLER said that he agreed with Dr. Raw in regarding scrofula and tuberculosis as essentially different. He had been led to this conclusion by having to estimate the degree of increased liability to tuberculosis of those with cervical scars dating from early life. He had rarely seen cases of pulmonary tuberculosis in which there were neck scars. That some kind of immunity to pulmonary tuberculosis was conveyed by the other form acquired in early life might be one explanation. Dr. Marcus Paterson had told him that he had examined some hundreds of cases of pulmonary tuberculosis at the hospital to which he was attached, and only a very small proportion of the patients had evidence of having had glandular tuberculosis in early life. He had never seen a case of pulmonary tuberculosis in which he was convinced that tuberculin had done any good, but this did not invalidate what Dr. Raw had advocated. He thought that the evidence pointed to pulmonary and glandular tuberculosis being different infections. Eighty-five per cent. of cases of glandular tuberculosis were bovine, and all, or nearly all, cases of pulmonary tuberculosis were caused by the human bacillus.

Dr. **Weber** said that the therapeutic use of tuberculin had now been almost given up all over the world, even in the country from which it had originated. Tuberculin, unfortunately, did not really produce immunity to tuberculosis (that is to say, to tubercle bacilli), though it could produce immunity to tuberculin. Granting that what Sir James Kingston Fowler had said was true (as he thought future statistics would ultimately prove it to be)—namely, that persons with "scrofulous" scars from infection with bovine tubercle bacilli in childhood were comparatively immune to grave pulmonary tuberculosis (from human tubercle bacilli), he did not take a quite hopeful view, from the therapeutic standpoint, as to the probable results of Dr. Raw's method of treatment. There was a great difference between persons who had been attacked by bovine tuberculosis as children and those injected with Dr. Raw's vaccines. In the former case the patients had been inoculated, and actually infected, with *virulent* bovine tubercle bacilli over a long period, and even they were not quite invariably protected from death by subsequent tuberculosis of the lung (human tubercle bacilli). What, then, might the result be of injections of Dr. Raw's bacilli, which had altogether lost any virulence? He (Dr. Weber) thought that the immunity produced even by actual inoculation with Dr. Raw's *living* cultures of non-virulent tubercle bacilli would probably last only a very short time. Much more proof to the contrary was needed.

Dr. W. **Camac Wilkinson** said that the only way to prove the incidence of bovine and human tuberculosis was to take a long series (300–400) of post-mortem cases and work out from the tuberculous lesions the existence of one or other or both varieties of bacillus. The two varieties could exist in the same individual in his opinion. Gaffky had found that in 300 consecutive post-mortem examinations on children there were 57 cases of fatal tuberculosis, and in 55 out of the 57 the tubercle bacilli were of the human type. In a further series of 100 consecutive post-mortem examinations on children who had died in a general hospital 21 per cent. of the deaths were due to tuberculosis, and only one was due to the bovine bacillus. In Japan the cattle were immune to tuberculosis. Where did the children get the disease? In Japan tuberculosis was relatively greater than in England. Dr. Wilkinson then spoke of the favourable experience he had had with tuberculin.

Dr. C. W. **Hutt** said that Stanley Griffiths had pointed out that a very much larger number of children exhibited bovine tuberculosis than Dr. Wilkinson had said.

Dr. **Raw** said, in reply, that he wished to establish the general principle that we had to deal with two infections. He had found that tuberculin prepared from cultures of low virulence was much safer for the patient than that prepared from virulent cultures. He had performed 1800 post-mortem examinations on patients who had died from tuberculosis, but had never seen tuberculous meningitis occur in a case of primary pulmonary tuberculosis.

WAR SECTION.

Medico-Military Training.

A meeting of this section of the Royal Society of Medicine was held on March 14th, when Colonel H. E. R. **James** read a paper on the best form of instruction for medical students to fit them to take their part in case of national emergency. The paper is published in full in the present issue of The Lancet.

Mr. H. **Wansey Bayly** considered that there was urgent need for all medical students to receive some course of instruction in duties which they might be required to fulfil if called upon for war service. He very much doubted the reliability of Colonel James's statement that in future wars only those medical men belonging to the Reserve of Officers, or the Territorial Force, would be called up, as he believed that in the future, as in the past, temporary officers would have to be employed. Lack of proper instruction to M.O.'s, either before the war or during their military service, had entailed much unnecessary loss of life, and loss in the value of medical officers' services, and he stated that neither during his service at home, nor during his service as battalion medical officer in the Guards' Division, nor as medical officer to a brigade of artillery in France, had he ever received any instructions in his duties, with the result that he, in common with many other Territorial and Temporary officers, had felt that they had not been so useful as they would have liked to have been. It was true that orders and instructions were constantly being received on paper from headquarters, but such orders were liable to get lost or destroyed. The inspection and supervision were almost nil, so that it depended entirely upon the keenness of the medical officer as to whether he made any attempt to carry out the orders that he had received. Many medical officers seemed to consider that their duties consisted in attending to the sick when at rest, or to casualties when in the line, and failed to realise that their chief value lay in teaching preventive medicine, in carefully supervising the sanitation and hygiene of their unit, and in giving instruction in these matters to the officers and men.

In order to endeavour to obtain continuity in sanitation he had drawn up some battalion sanitary standing orders which, with the sanction of his A.D.M.S., were adopted by his battalion and which were published in The Lancet of June 16th, 1917, and, he believed, were adopted in a few units. He considered that the cause of medical students' and medical men's reluctance in joining medical units at the present time could be summed up in one word—distrust—distrust of the War Office, based on many bitter memories. He considered that the instruction could be better carried out by the civilian teachers and civilian teaching hospitals than by the R.A.M.C., as the really essential portion of such education was very simple and did not take long.

Civil and Military Training Contrasted.

Mr. T. B. **Layton** considered that the duties of the R.A.M.C. officer have in the past differed from those of his civilian colleagues in three ways: (1) He has been employed in preventive medicine to an extent unknown to members of the civil branch of the profession; (2) he is always engaged to a certain extent in administrative work; (3) the sick and wounded are not his personal patients, but they are the patients of the corps, coming under him for a short time only. He (the speaker) considered it was necessary to organise our instructions on the principle of teaching the students such subjects as apply especially to military work, to which insufficient attention is at present paid in the curriculum. In his position as an officer the surgeon had certain duties common to other branches of the Service, such as procuring food, clothing, and quarters; the power to move bodies of men rapidly, which is known as drill; and a knowledge of military law. These portions of the student's education should be taught as an irreducible minimum or not at all. There are plenty of other subjects to occupy such short time as he can spare, which are of vital importance to him as soon as the necessity arises. Advances of surgery in future wars would depend almost entirely upon the development of medical tactics, and unless we can apply to mobile warfare the six-hour ideal from wound to operating theatre all advances of civil surgery will be applied to military surgery in vain. For the junior ranks of the R.A.M.C. Mr. Layton would say it was enough if they studied the subject of shock and collapse in its relation to the transport of wounded. Hygiene of the march cannot be too strongly impressed upon anyone. He would have the students study it particularly in relation to the weight carried by the soldier and the problem of water-supply. He foresaw a great struggle with the combatant soldier in the future on the weight problem, and every medical man should be in the position to give firm advice on this point. The examination of recruits should be limited to men who have had training therein. The nation is, he believed, now spending thousands of pounds weekly on pensions to men with pre-war disabilities, which were not noticed on their enlistment forms (B178), or as the result of badly done boards (B179) in the early stages of demobilisation. He would urge that the chief subjects to be taught under the head of sanitation are those of food and of the louse problem. Besides that, he would teach them how to make a sanitary inspection with firmness but politeness. If the medical student learns all these things, he will have no time to study the army form on which to claim his allowance, how to obtain a tablet of aspirin, a bottle of brandy, a bar of soap, or a tin of pork and beans—he will learn these quickly when he once begins.

Opportunity for Military Training in the Curriculum.

Dr. C. H. **MILLER** thought that it would be possible for teachers in civil hospitals to point out the objects for which the Army Medical Service existed. In the field it was the minor malady and the slight wound that were important. A man who had sustained a compound fracture of the femur was useless to the army for many months, if not permanently; and therefore, from the army point of view, he was less important than a man suffering from I.C.T. It was not only incumbent on the student to learn about disease in all its aspects, but to realise that it was part of his duties to keep as many men fit as possible.

Dr. H. L. **EASON** considered that civilians were trained to consider the individual, whereas the army medical officer had to consider both patients and diseases in the mass. He thought it was impossible to give efficient instruction in hygiene and State medicine during the undergraduate's curriculum, as it was already overcrowded; but that some scheme would have to be devised whereby the claim for a doctor's service after qualification is possible for a period of 6 to 12 months for the purpose of army training. It had not always been realised by the R.A.M.C. that the day had gone by when they could expect a medical man to turn his hand to anything; this was a day of specialism, and some scheme must be devised whereby in a national emergency the chief medical officers should be allotted to posts for which their peculiar training fitted them. He was sure that if medical men were to be trained to fit themselves for national emergency, any such scheme devised for this purpose must be to a large extent compulsory.

Several other members of the section took part in the discussion, all agreeing that the really necessary education should be as simple in character as possible, and that the elements of war sanitation and hygiene were essentials, and expressing the opinion that there would be difficulty in obtaining recruits until the memory of various grievances (such as higher pay of Temporary over Territorial or Special Reserve Officers; the employment of specialists in ordinary routine work, while persons of no special knowledge were given positions as specialists; the payment of war gratuities on substantive rather than acting rank; promotion for reasons other than competency, &c.) had become dim through the passage of time. The discussion was a most interesting one, as contrasting the opinions and views of the Regular, and Territorial and Temporary branches of the Service; and the practical unanimity with which all those speakers who had held Territorial or Temporary rank agreed that the present lack of enthusiasm for military service amongst civil medical men and medical students was largely based on undeniable grievances during the late war.

SECTION FOR THE STUDY OF DISEASE IN CHILDREN.

CONGENITAL SYPHILIS.

AT a meeting of this section of the Royal Society of Medicine, held on March 16th, Dr. F. S. **LANGMEAD**, the President, being in the chair, the discussion on Congenital Syphilis, adjourned from Feb. 25th, was reopened by Dr. H. **MORLEY FLETCHER**, whose paper appeared at length in THE LANCET of March 26th.

Post-natal versus *Ante-natal Treatment.*

Dr. **LEONARD FINDLAY**[1] said that he would like in the first instance to draw attention to the Wassermann reaction when properly carried out as being undoubtedly the most important aid to the diagnosis of the anomalous and late varieties of congenital syphilis. In support of this contention he referred to an analysis of 1000 reactions performed for him by Dr. R. M. Buchanan of Glasgow, in which the clinical and serological findings were contrasted. Cases of undoubted and suspicious early syphilis were divided into four groups according to the degree of clinical certainty of syphilis or no syphilis. In the cases clinically definitely syphilitic the reaction was positive in 98 per cent., whereas in those definitely non-syphilitic it was negative in 100 per cent. These figures, too, were in close agreement with those showing the behaviour of the reaction in the mothers of syphilitic and non-syphilitic children. Statistically, then, a positive reaction meant syphilis, and a negative reaction no syphilis, at least in the presence of active manifestations of disease. The serological test was, in fact, more frequently in agreement with the pathological lesions than the Widal reaction in the case of enteric fever on the finding of the tubercle bacillus in phthisis pulmonalis.

In view of the above the Wassermann reaction should be a great help towards deciding if a particular pathological process possessed a syphilitic basis. It would be curious if it were only the anomalous forms of the disease that gave a negative reaction, and it was difficult to understand how the syphilitic infection could so profoundly alter the child's nutrition or call forth radical changes in various organs and yet fail to induce the usual serological changes. Yet this was what many writers inferred to happen. In the presence of a negative reaction one demanded very strong clinical proof that the diseased condition was of a syphilitic nature. As the reaction persisted long after all clinical manifestations had disappeared, it should be our most delicate test of cure and a good gauge of the efficacy of the different methods of treatment of congenital syphilis as practised to-day. Treatment with mercury alone was most unsatisfactory, because a large proportion of the youngest patients died; in his own experience 70 per cent. of these under 3 months of age.

With the combined treatment with salvarsan or its allies and mercury the mortality of the young patients had been greatly reduced, only some 20 to 30 per cent. dying, but unfortunately, at least as evidenced by a persistently negative reaction, a cure was only obtained in a proportion of the cases. In children under 1 year of age 8 per cent. could not be cured with as many as 14 injections and in children over 1 year of age a cure could not be obtained in 50 per cent. of the cases. Such a state of matters was one with which no one can rest satisfied and contrasted very markedly with the results of ante-natal or prophylactic treatment, by means of which he had obtained 100 per cent. of successes—at least the children had never reacted positively to Wassermann's test nor had they presented any signs of the disease, even when observed over as long a period as seven years. Perhaps the most striking feature of ante-natal treatment was that these women continued to bear healthy non-syphilitic infants, though no further antisyphilitic treatment had been instituted. Ante-natal treatment was undoubtedly the treatment par excellence, and should be encouraged by us in every manner possible. In his opinion this implied notification. By ante-natal treatment all miscarriages and still-births could be avoided and the health of the future progeny ensured.

---

[1] Dr. Findlay's remarks were made at the meeting on Feb. 25th, but were not received in time for insertion in our issue of March 5th

Ante-natal and Neo-natal Disease.

Mr. **JOHN ADAMS** confined his remarks to ante-natal syphilis, and the disease as it occurs in the newly born.

Congenital syphilis, he said, was rarely seen clinically in young people and adults, and the treatment of such cases was unsatisfactory, whereas the treatment of ante-natal syphilis and post-natal syphilis in infants was most encouraging. The best time to treat mother and child was at the earliest possible moment; the youngest baby he had treated was an hour old. The results were seen at once, and there was no secondary eruption. The Wassermann reaction rarely reverted to positive, and for the past three and a half years his cases were tested every three months. The year ending August 31st, 1920, was a particularly successful one at the Thavies Inn Venereal Clinic for Pregnant Women. Thirty-seven mothers had been admitted with syphilis, 37 babies had been born alive, one with a positive Wassermann reaction, 36 with a negative reaction; none of the babies died of syphilis, and no fœtus was stillborn from syphilis. The babies were treated according to a special scheme, which had been found most satisfactory, by intramuscular injections of galyl in glucose, intramuscular injections of mercury, and mercury by the mouth.[2] He thought that, except in the most expert hands, injection into the superior longitudinal sinus or external jugular vein must be difficult, dangerous, and disastrous. Mercurial treatment alone was too slow, but the results of galyl were seen in the baby within a few hours, and in adults within an hour.

When women were infected with syphilis during the seventh month of pregnancy the baby was healthy, which bore out Dr. Routh's view as to the protective part played by the syncytial cells; besides this, the lipoids appeared to have a protecting influence on the fœtus. Dr. Routh, in his lecture on Ante-and Post-Natal Syphilis before the Harveian Society in January, 1918, stated that, according to his estimation, 27,000 deaths occurred annually in England and Wales alone in the ante-natal period and the week following birth as a result of syphilis. It would seem that the reason why we saw so few children and adults affected by congenital syphilis in clinics was because they had ceased to exist.

Mr. Adams thought that venereal disease lying-in centres should be established in every town with medical officers specially appointed to look after the cases. He looked forward with confidence to the future, expecting that the wastage of infant life from syphilis would almost be abolished.

Dr. **REGINALD JEWESBURY** gave the results of the first 12 months' experience in the venereal clinic for children at St. Thomas's Hospital. These results are about to be published.

Infection from the Mother.

Mr. **J. E. R. MCDONAGH** said that if a woman contracted syphilis before the fifth month of pregnancy the child always contracted the disease; if she became syphilitic during the sixth and seventh months the child was affected by congenital syphilis in about half the cases, and if during the eighth and ninth months the child escaped.

Many of the infants who escaped infection in utero acquired syphilis by direct contact with their mothers soon after birth, and quite a large number of cases of so-called congenital syphilis were really cases of acquired. When a woman contracted syphilis, if she should have nine pregnancies, the first and last three were most likely to result in abortions, stillbirths, or in the birth of apparently healthy children who would show symptoms before the sixth week. Non-syphilitic children were most likely to be born in the middle. This was also true of a woman who conceived and contracted the disease from the embryo (conceptional syphilis). Although this was a general rule it must never be forgotten that once a woman had borne a syphilitic fœtus she was ipso facto herself a syphilitic and therefore capable of infecting all her future offspring, even if the father had never had the disease. A syphilitic woman, therefore, should be treated throughout the whole period of each succeeding pregnancy, irrespective of the amount of treatment she had already undergone.

With regard to the effect on the child of the treatment of its syphilitic mother, he said that, provided that the mother had had treatment throughout the whole of pregnancy, or when the disease was first diagnosed, one might expect the birth of an apparently healthy child. Without being able to give the exact percentage, he had formed the opinion during the last ten years that the majority of those apparently healthy children were really syphilitic. They did not develop symptoms before the sixth week, as used to be the case in the pre-salvarsan era, but at the age of 4 years or more developed eye, ear, or nervous troubles which did not respond to treatment. The syphilitic child in utero might be so influenced by the treatment of its mother as to behave like an acquired syphilitic whose response to the disease had been cut so short by treatment that when a recurrence appeared the lesion aped the primary sore. He now always treated for two to three years every child born of a syphilitic mother, however healthy at birth it might appear to be. Whether such a course would prevent syphilis hereditaria tarda only the future would show.

Value of Serological Tests.

As to whether pathological tests were of any value in discerning which children were syphilitic and which were not, he said that it was the rule for children born of treated syphilitic mothers to be serologically negative and to remain so till clinical manifestations appeared, even if they did not appear for some years, therefore a negative complement-fixation test could never be held as signifying that the child was not syphilitic. In cases in which the test was positive during the first months treatment only very slowly rendered it negative, and without treatment it tended to become negative about the age of puberty. When the test became positive for the first time three or four years after birth, it remained positive for the rest of the patient's life irrespective of the amount of treatment he or she underwent. If a mother gave a positive reaction at the time of birth the umbilical blood was usually positive as well; and even the infant's blood might be positive, although the child was not necessarily syphilitic, as, for instance, when the mother contracted the disease at the eighth month. Therefore a positive reaction given by a child at or soon after birth was not proof positive that the child was syphilitic.

Mr. McDonagh thought that we should see less early congenital syphilis in the future, but much more syphilis hereditaria tarda, especially in cases of late congenital nervous syphilis. It was impossible to say yet whether treatment of both the mother and the child would prevent this. On the other hand, it was possible to assert that pathological tests would neither help in prognosis nor indicate whether a case was cured or not.

Interstitial Keratitis.

Mr. **H. NEAME** discussed the results of treatment in 38 consecutive cases of interstitial keratitis. The treatment consisted of one, two, or three intravenous injections of novarsenobillon or diarsenol. Mercury by the mouth was given simultaneously.

Of the 38 cases 24 were suitable for inclusion in a group with a view to estimating the value of the treatment. In this series the arsenical preparations combined with mercury had not prevented five patients, who had come for treatment with keratitis in only one eye, from involvement of the second eye. Three had still only one eye involved. The evidence as to whether treatment prevented other complications, such as choroido-retinitis, was insufficient. There were five cases with this complication in the series. Three of these were old cases; one had been under treatment for interstitial keratitis in one eye, the other eye having been diseased six years before; the last had had the disease and was treated by other means for nearly a year before arsenic injections were given. Of the rest of the series there were only three in which choroiditis was possibly present. It was probable that the arsenical preparations had an effect on the choroid, since it was a very vascular structure. With regard to the effect on interstitial keratitis already established, it would appear from the visual acuity results in this series and from Wallis's experiences in 1913 that arsenical preparations had some influence in improving the final vision and in its more rapid attainment. With the growth of prophylactic treatment during pregnancy it was possible that the incidence of interstitial keratitis, like that of other manifestations of congenital syphilis, would dwindle.

Changes in the Teeth.

Mr. **A. T. PITTS** spoke of the teeth in congenital syphilis, and said that although we were not now so completely dependent on clinical manifestations for diagnosis since the introduction of the Wassermann reaction, yet the presence of certain dental dystrophies peculiar to congenital syphilis was still a sign of considerable positive value.

---

[2] Royal Society of Medicine: Section of Obstetrics and Gynæcology, Nov. 7th, 1918; Nov. 4th, 1920; THE LANCET, 1918, ii., 707, and 1920, ii., 990.

The teeth which showed characteristic modifications were the upper central incisors and the first permanent molars. The former were described by Hutchinson in 1858, and the latter appeared to have been recorded by Moon, the dental surgeon to Guy's Hospital, in 1878, and were often spoken of as Moon's molars. There were two elements in a typical "Hutchinson's" incisor, the narrowing toward the tip and the notch. The first indicated an alteration in the whole architecture of the tooth, and would suggest that before calcification commenced the cells of the tooth germ were affected by the syphilitic virus. The notch would appear to be due to a true hypoplasia, due to some interference with calcium metabolism, and comparable with the hypoplasia seen in rickets and other disorders of childhood. Mr. Dolamore had suggested that this might not be an essential part of the syphilitic manifestation, but due to some intercurrent illness of malnutrition. Stein had stated that there were four stages in the life-history of a syphilitic tooth: (1) a diminution in breadth and an area of badly formed enamel at the cutting edge on eruption; (2) wearing of the cutting edge, which left the typical notch; (3) obliteration of the notch from wear to only a slight bevel on the anterior edge; and (4) obliteration of the notch and so much of the tooth that its diagnostic value vanished.

It must be admitted, however, that though this grouping of the life-history of the Hutchinson tooth was attractive, its clinical history was not absolutely conclusive. It should be remembered, however, that there might be an early stage when the notch was absent, and an undue insistence on its presence might blind an observer to the significance of a tooth unnotched, but with a marked narrowing toward the cutting edge. In his opinion, the enamel of syphilitic teeth was usually normal and showed no greater liability to caries than any other teeth. The view that mercury was the cause of hypoplastic teeth was not generally held nowadays. The lateral incisors of the upper jaw and the lower incisors might also show the characteristic shape, but much less commonly, and only rarely without the upper centrals being affected. Moon's teeth also showed a diminution in breadth towards the masticating surface, and shared the characteristic alteration in their architecture. The cusps were stunted and rounded; Moon described them as "dome-shaped," and an American writer had recently described them as the "mulberry" molar. Their appearance was equally characteristic with Hutchinson's teeth, but had to be distinguished from hypoplasia. In syphilis the molar tooth seen from the side view was dome-shaped, almost conical, and without the bulge of enamel usually present. The masticating surface was a flat plateau on which the rounded stunted cusps projected like small beads.

Another sign of congenital syphilis described by Sabouraud was said to affect the upper first molars only, and consisted of an accessory cusp on their internal surface at the anterior corner. This was a frequent malformation and often existed alone in a mouth whose dentition was otherwise regular and normal. It occurred in so large a proportion that it must be an anatomical variation, and he thought it was without pathological meaning. The same variation was sometimes found in the upper second deciduous molar. With regard to the milk dentition he was doubtful whether there was any condition which could be regarded as truly diagnostic of congenital syphilis, although the changes might be suggestive. A few cases of Hutchinson's teeth in the milk dentition had been recorded, among which were 27 cases recorded by Parrot, who, however, regarded rickets as a syphilitic manifestation. Calcification of the deciduous incisors commenced at the sixteenth to eighteenth week of intra-uterine life, and syphilis attacking the fœtus at that early stage was more likely to cause its death. This was probably the reason why a dental manifestation in the milk dentition was so rare. He suggested that some of the examples of Hutchinson's teeth recorded in the deciduous dentition might really have been cases of caries which had produced notches.

One disorder found in milk teeth, undoubtedly associated in some cases with congenital syphilis, was hypoplasia. Out of 4000 children he had only been able to collect 20 cases. It must be caused by factors operating before birth, and as syphilis was the disease which was most important at this period, it was reasonable to suppose that it must be included among the diseases which caused defective development of the deciduous teeth. There were, however, other causes, such as malnutrition of the mother, and a lack of vitamines in the maternal diet. Such must be common in mothers of the poorer classes, and yet hypoplasia of the milk teeth was very rare. It was of interest that out of his cases four occurred in congenital syphilitics, and in these the hypoplasia was especially well marked.

Without being dogmatic on such scanty evidence he would like to suggest that on *a priori* grounds congenital syphilis should be regarded as one of the causes of hypoplasia of the milk teeth, and that any well-marked case should arouse a suspicion sufficient to warrant further investigation.

Infrequency in General Practice.

Dr. RONALD CARTER said he had had 25 years' experience in general practice and 14 years at infant welfare work, and congenital syphilis was, in his experience, a comparatively rare disease.

He referred to a passage in Dr. Amand Routh's address last November on Latent Syphilis, in which he quoted some statistics of Dr. Helen Campbell, chief medical officer of the infant department of Bradford, on the frequency of congenital syphilis in industrial cities. Of 2172 infants born in 1918, 1606 were registered; the infant mortality was due to congenital syphilis in 80 per cent. of the deaths. Dr. Campbell ascribed these startling figures "to the fact that congenital syphilitic infants are peculiarly selected for attack by respiratory, gastro-intestinal and specific infections, such as measles, &c., which kill them in much larger numbers than infants not so affected." Dr. Carter pointed out that no pathological report of the cases was given and that, therefore, these statistics were of no value. They could not in any way represent the frequency of the disease amongst the industrial population.

He regretted that statistics which were so unreliable should have been quoted.

A Summing-up.

The PRESIDENT said that in the few minutes that remained he would not attempt to summarise the discussion, but would mention one or two important conclusions which could be drawn. On the diagnostic side it was clear that the general opinion was that a positive Wassermann reaction was good evidence of the presence of syphilis, except within a short time after birth, whereas there was some difference of opinion as to the value of a negative reaction. He thought that Mr. O. L. Addison's contribution had shown conclusively that what was generally known as syphilitic epiphysitis was really a manifestation which was very generally distributed through the osseous system, a conception of the disease which was not as well known as it should be. The importance of X rays therefore in diagnosis, especially on the surgical side, was evident. Sir Humphry Rolleston, as also Dr. Morley Fletcher, had broken a great deal of new ground, and had stimulated us to the closer investigation of a large number of disorders of doubtful ætiology. He was sure that they would be the first to agree that some time must elapse before we could postulate the influence of syphilis in their production. Of extreme practical importance was the general agreement upon the value of antisyphilitic treatment of the pregnant mother. The discussion had been a very valuable one in many ways, and if it had done no more than bring this point of view decisively before the profession it had played a very useful part.

Sir HUMPHRY ROLLESTON, in his reply, said that he thought that some of the most important contributions to the discussion were those on the special subjects. There was clearly a difference of opinion as to the incidence of the disease. The view taken by Dr. Morley Fletcher that there had been a change in type was very interesting.

SOUTH-WESTERN OPHTHALMOLOGICAL SOCIETY.—The meeting of this society, held on March 9th at the Bristol Eye Hospital and presided over by Mr. E. Richardson Cross, was well attended, in spite of the scattered nature of the area covered by the society. The morning was devoted to examination of a number of interesting cases, among which may be mentioned one in a child, shown by Mr. A. N. Godby Gibbs (Bristol), which illustrated very well the difficulty of distinguishing between glioma and pseudo-glioma retinæ. After luncheon the meeting was addressed by Mr. R. J. Coulter (Newport) on Some Squint Problems. In this he adopted heterodox views in order to provoke discussion, and a good debate ensued.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

AN ordinary meeting of this society was held on March 18th at 1, Upper Montague-street, W.C., Dr. F. E. **FREMANTLE**, M.P., the President, being in the chair. Forty-one new members were elected.

Dr. A. T. **NANKIVELL** (M.O.H., Poole) read a paper on

The Relation of the Laboratory to Preventive Medicine.

He spoke of the present-day cry for "economy," and said that it would be well if the people would rather ask for "science," for where the voice of the scientist was heard economy and thrift had followed. If the public would follow their scientific advisers, the health, and therefore the prosperity, of the community would be vastly bettered. The people were very ignorant of the science of public health. They knew little of the triumphs over malaria, plague, cholera, enteric, diphtheria, anthrax, and tetanus, and while they were aware that the Panama Canal existed, they were ignorant of the work of the scientists who conquered disease and made its construction possible. The first person to realise the value of the laboratory to the health department was Dr. D. S. Davies (M.O.H., Bristol), who was a pioneer in the large scale bacteriological examination of diphtheria contacts. The speaker heard with regret that some M.A.B. hospitals were discharging their diphtheria cases without swabbing. In Poole, where active swabbing was performed, including all sick school children and all cases of sore-throat, purulent nasal discharge, and discharging ears, the case mortality from diphtheria was only 3 per cent. Perhaps the laboratory was most useful in connexion with the diagnosis of diphtheria and tuberculosis. To-day in England and Wales practically all counties and county boroughs had their own laboratories or arrangements with laboratories at hospitals or universities, but many smaller towns and rural districts had no adequate arrangements. There was no doubt that with adequate staffing small laboratories were most useful, especially in saving time in connexion with diphtheria swabs. Every whole-time M.O.H. should have a laboratory to deal with diphtheria, sputa, ringworm hairs, blood, fæces, and water samples. In the larger places they might undertake all pathological work, including morbid histology and animal inoculation. General practitioners made much use of such facilities, and small fees might be charged, which were welcome in place of the fancy prices charged by some laboratories. In Poole the laboratory at a flat rate of 1s. 6*d*. per specimen was almost a paying concern. A fully-equipped county laboratory might extend its scope still further to agricultural bacteriology, for example. Chemical analysis should be left to the public analysts. The Dawson Report foreshadowed laboratories at the primary health centres, but Dr. Nankivell suggested that the family doctor, in respect for whom he yielded to no one, is but rarely competent to manage a laboratory, and that it would be better to continue to use the existing laboratories of the public health departments. The crying need of to-day was research and a close coöperation between the statistician, the epidemiologist, and the laboratory. Every M.O.H. who has a laboratory might undertake some research. To them was given the opportunity, and they would only have themselves to blame if others took the chance which they had missed.

Dr. C. W. **PONDER** (Pathologist and Assistant M.O.H., Kent) said that at his county laboratory they examined 20,000 specimens last year. They served a population of one million, and 450 doctors were continually sending specimens. No charges were made, and the inclusive cost for a year, after the deduction of £570 received back on account of venereal work, was £1250. The charge at a commercial laboratory would have been over £3500. He was not quite so sure of the value of swabbing in dealing with the prevention of diphtheria in large populations, though he realised that it gave good results in isolated communities. A special use of the laboratory was in educating the practitioner. Bacteriology was of great importance in dealing with typhoid fever, and he instanced an outbreak at Strood from infected water-supplies which was nipped in the bud by action taken by Dr. W. G. Howarth following upon the discovery in the laboratory of four simultaneous positive Widal reactions from that town. He thought that for poor people the public health laboratory should do non-infectious work, such as vaccines, sections, and blood examinations. Why should not the present local and county laboratories be linked up with the primary and secondary centres of the Dawson Report? In connexion with diphtheria swabs, delay in the post was a great trouble. He found that nearly 90 per cent. of positive diphtheria swabs were diagnosable by direct smear before culture, and this method should always be practised.

Dr. J. A. **WATT** (M.O.H., Ilkeston, and T.O., Derbyshire) said that the Derbyshire laboratory also dealt with the whole county. No charges were made. He agreed with the practice of taking no swabs from diphtheria cases on discharge from hospital. He believed that the cases which persisted in giving positive swabs over a long period did no harm. In typhoid fever it was most important to test the blood of all cases of illness in the family. He was in favour of attaching small laboratories to the primary health centres, if started.

Lieutenant-Colonel J. A. **ANDERSON**, R.A.M.C. (Assistant Director of Hygiene, R.A.M. College), stated that in the army there was better coöperation between the hygienist and the pathologist than in civil life. Close intimacy was essential, and chemical, entomological, and biological laboratories were needed as well as bacteriological. In Salonica he had found all these necessary in dealing with malaria. Through laboratory work they had found that the application of cresol to pools, &c., gave better results than the oil which was available. The education of the general practitioner was more important than of the sanitary specialist in this respect. The speaker wondered whether the mobile laboratories, which were so valuable in the war, would not also be useful in civil practice.

Dr. E. W. **GOODALL** (Metropolitan Asylums Board) agreed that every health authority should have a well-equipped laboratory. In collaboration with the late Dr. Washbourn he had had a good deal to do with the inclusion of bacteriology in the curriculum for medical students. He felt, however, that they had not got from bacteriology all that they had at one time expected. At his hospital they did not swab diphtheria cases on discharge. He took this course with a full sense of responsibility and in the knowledge that the cases were carefully watched by the M.O.H. For many years he had insisted on three negative swabs before discharge, but the results under that system had been no better, and return cases as common. Swabbing had been as devoid of results in connexion with post-scarlatinal diphtheria. The swabbing of all admissions and the isolation in a separate ward of those with diphtheria bacilli had not made the least difference to the incidence of diphtheria in the scarlet fever wards. They found that 10 per cent. of the scarlatinal admissions were reported as positive and had to be isolated. He questioned how many "positives" were really virulent bacilli. There was work which showed that only those from recent cases of diphtheria were virulent. The needless discovery of harmless positives was a nuisance. The matter was certainly one which urgently needed settling. He thought that valuable statistical comparisons might be made between M.A.B. hospitals having different practices in regard to swabbing. In connexion with the remarks on the laboratories proposed in the Dawson Report, he reminded the meeting that these were proposed for clinical and not for public health purposes.

Surgeon Rear-Admiral P. W. **BASSETT-SMITH** (R.N. College, Greenwich) said that the greater part of naval medicine was preventive, and that laboratory work was of the greatest importance. They had laboratories on all great ships and in all hospitals. The medical personnel was well versed in laboratory procedure, and the hygiene officers in close touch with the laboratories. They regarded it as important that no diphtheria cases should go back to the crowded conditions on ships until three negative swabs had been obtained. Where they had positive results and no clinical signs, virulence tests were done. At Greenwich School they practised widespread swabbing during the occasional diphtheria outbreaks. The laboratory was very important in the discovery of typhoid carriers. Laboratories should not be too small, as numerous places cannot all have expensive equipment and trained bacteriologists.

Dr. R. VEITCH CLARK (M.O.H., Croydon) had found that it was a sound economic proposition to run a fully-equipped laboratory for a district of about 200,000 population. In closed communities, such as schools and orphanages, he had been able by examination and swabbing to stop persistent outbreaks of diphtheria. A laboratory was essential both for clinical purposes and for administrative preventive medicine. He had greatly regretted, in connexion with two outbreaks of infective jaundice, that he had not a well-equipped laboratory at his disposal. He instanced dental decay, pyorrhœa, pseudo-rheumatic conditions, and the use of vaccines in respiratory diseases as requiring research. It was also required in connexion with school medical work, which was too much concerned at present with the mere piling up of statistics. M.O.H.'s should make special note in their annual reports of such conditions and epidemics as demand research, and of the difficulties experienced.

Lieutenant-Colonel F. HARVEY, R.A.M.C. (Deputy Director of Pathology, War Office), remarked that Dr. Nankivell's laboratory work in France was well known to him. He referred to the early systematic bacteriological work at the R.A.M. School at Netley. In 1898 they had there an excellent course with which was associated the names of Sir Almroth Wright, Sir David Semple, Sir William Leishman, and Sir William Horrocks. In the army there was a very close link between public health and the laboratory.

Dr. S. MONCKTON COPEMAN (Ministry of Health) said that too much prominence had been given to swabbing and "carriers" in diphtheria, and great expense was often wasted in this connexion. Seven per cent. of the population harboured diphtheria bacilli (so-called) in their throats. Virulence tests must be done, and if virulent the result was much more important. What was to be done with the carrier when discovered? Sections of the tonsils showed that the bacilli were usually deep in the crypts and not on the surface, and therefore surgery should be thought of. Recent American work claimed value for the testing of communities by the Schick reaction and the injection of toxin-antitoxin mixtures to produce immunity in those who were found by this reaction to be susceptible. The immunity thus produced was said to last three or four years (instead of a few weeks only, as when antitoxin only was injected), and the likelihood of anaphylaxis was said to be less. The Schick reaction could be tested again to determine whether the immunity had persisted. The results of the reaction indicate that many acquire immunity in a diphtheria outbreak without getting the disease in clinical form. Experiments were to be carried out shortly at Bristol on these lines. Where there was a good university laboratory Dr. Copeman thought it was better to make use of it than to start one independently in the health department. In any case he did not approve of the multiplication of small laboratories.

Dr. T. SHADICK HIGGINS (M.O.H., St. Pancras) doubted whether even the virulence test was sufficient to substantiate the dangerousness of so-called diphtheria carriers. He instanced work which he had done at Birmingham in collaboration with Dr. C. J. Lewis, in which scarlatinal convalescents were found frequently to have in their noses diphtheria bacilli which on isolation proved to be virulent to guinea-pigs. These patients had not infected any members of their families with diphtheria, though many of them had caused return cases of scarlet fever.

Dr. HERBERT JONES (M.O.H., Herefordshire Combined District) said that he now discouraged the swabbing of diphtheria contacts, and that the results were no better than in the absence of swabbing. They must rely more on the virulence test. They might be doing harm in relation to public opinion by pushing such bacteriology too much to the front.

Dr. T. EVANS (M.O.H., Swansea) remarked that it was his practice in dealing with diphtheria contacts in schools to swab only cases with clinical signs, especially nasal discharge, enlarged glands, anæmia, or recent sore-throat. He questioned whether the Schick reaction could be applied to large populations. He instanced various directions in which laboratory research was needed, and claimed that there was no necessity for separate laboratories for bacteriological and pathological work.

The PRESIDENT observed that the discussion had centred too much round the subject of diphtheria. He said that the value of laboratories in military medicine had been proved over and over again. At the present time our difficulty was that we knew far too little to enable us to interpret bacteriological results, and the chief need was for research. The M.O.H. could spend his time most profitably in administrative work, and should not devote himself overmuch to petty laboratory work. There should be only one laboratory for a given area, which should do all the civil work required in the district, as well as naval and military work. They must press ahead, but go very carefully. Medical students should be turned out in the future with complete bacteriological knowledge.

Dr. NANKIVELL briefly replied.

Meeting of the Welsh Branch.

A meeting of the Welsh Branch of the Society of M.O.H.'s was held at Shrewsbury on March 19th, Dr. Colston Williams in the chair. A paper was read by Dr. Howard Jones in which he described steps taken in Newport to improve existing housing conditions, first by persuading occupiers to carry out improvements recommended by the health authorities, and then, through frequent inspection, by insisting on tenants maintaining hygienic conditions. Great advance in the direction of raising the amour propre of the tenants was stated to have been obtained without proceeding to legal compulsion.

MEDICAL OFFICERS OF SCHOOLS ASSOCIATION.

Corporal Punishment in Schools.

AT a conference of this Association, held on March 18th, representatives were present from every class of educational institution. Mr. R. C. ELMSLIE, the President, referred to a previous meeting at which the medical aspects of the matter had been discussed and a resolution passed:—

> "In view of the evidence of damage from caning on the hand, and the possibility of consequent impairment of function, this society is of opinion that caning on the hand should be forbidden."

That resolution had been sent to the Home Office, the Board of Education, and the Ministry of Health.

Dr. E. H. T. NASH referred to instances of injury he had seen, and to a questionnaire he had sent round, to which there was an almost unanimous reply that whilst corporal punishment was an occasional necessity it should never be by caning on the hand. He advocated the tawse as used in Scotland, or else the cane on Nature's appointed place.

Canon A. A. DAVID, Headmaster of Rugby, thought punishments had much decreased in the past 20 years. Boys were better trained in preparatory schools and enjoyed much increased activities, so that masters could concentrate on positive encouragement and guidance rather than on the negative restraints and the rod. The less boredom existed the less need for punishments, but the element of fear was still necessary. If they caned they must hurt. He would not give up the stick, but it was not displayed or used indiscriminately.

Mr. C. W. CROOK, ex-President of the National Union of Teachers, said the elementary school teacher was at a disadvantage compared with the public school masters, as he had not the power of expulsion. The risks of caning had been much exaggerated. A body like the London County Council, responsible for a million children, would not have adopted caning on the hand with the restrictions they had without having some idea that it was the best form of punishment; and if not that, what was there for girls? An elementary school teacher who applied the rod to the back and raised wheals would soon find himself before the magistrate accused of brutality. He found the mere entry of a boy's name in the punishment book often sufficient. The time had not yet come when the medical profession could convince those responsible for elementary education that, if they punished at all, it must be elsewhere than on the hand.

Dr. W. GRIPPER, M.O., Royal Female Orphanage, found corporal punishment necessary. It was administered by the matron in camera. He could not say that caning on the hand was really bad.

Mr. M. J. RENDALL, Headmaster of Winchester College, regarded caning on the hand as a distinct blunder. They thought of the hand as sacred at Winchester and avoided damage even for a [short space of time. Punishment by prefects (senior boys) for quite trivial offences was very useful under careful regulation. The difference in opinion between the elementary school and public school view was remarkable and he hoped would be overcome.

Mr. W. SHARMAN, London Teachers Association, instanced a case where a teacher who had caned an insolent boy on the body had been punished himself by reduction of salary representing 60 times the amount he would have been fined had he assaulted the boy in the street.

Mr. J. R. ECCLES, Headmaster, Gresham's School, Holt, said he came into personal touch with all his 250 boys, and had not caned a boy in his own house for a dozen years. Caning was not degrading; it might be necessary, but should always be on the buttocks. He was wholly against birching or the frequent use of corporal punishment. He had used deprivation of games or privileges as a substitute punishment.

Miss DEANE, Kentish Town Secondary School, had doubts as to the efficacy of any corporal punishment. For girls in secondary schools it was unknown, and, from what had already been said, seemed rather an acknowledgment of failure on the part of the teacher.

Mr. L. LUMBY, National Union of Teachers, said that caning on the hand should never leave a bruise. If the tawse was recognised it would much simplify matters.

Mr. GUY KENDALL, University College School, used two-hour periods of detention, which had resulted in corporal punishment becoming obsolete, not because it was not wanted, but because there were persons who could not be trusted with it.

Rev. CECIL GRANT, St. George's School, Harpenden, commenced his teaching career strongly opposed to corporal punishment, but had reluctantly come to the conclusion that there were occasions on which it was essential. Detention and deprivation were, however, good substitutes on most occasions.

The PRESIDENT said that there had been practical unanimity amongst the medical members that the use of the cane on the hand was unjustifiable, and that they must condemn it whatever the teacher might say. He felt with the Head of Winchester that there was too wide an interval between the public and elementary school standards, and that the traditions which led to the present regulations in the public schools were of great value and should be a guidance to all teachers.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this society was held at the West London Hospital on March 4th, Dr. F. J. MCCANN, the President, in the chair, when a paper was read by Dr. BERNARD H. SPILSBURY on

Instrumental Abortion.

Dr. Spilsbury said that abortion was a practice by no means confined to civilised communities and instanced some of the crude methods in use amongst primitive races—e.g., pummelling the abdomen with stones. For the production of abortion the most effective methods were those in which violence or other physical agents were applied directly to the uterus. Success depended upon the amount of the local disturbance and to some extent upon the readiness of the uterine reaction, a factor which varied in different individuals.

The following were some of the commoner methods used:—

(1) Passing an instrument into the cervical canal or into the body of the uterus. In self-attempted abortion the favourite instrument was a hatpin, crochet hook, or a skewer. Skilled abortionists resorted to more suitable instruments, such as catheters. Without the requisite anatomical knowledge a woman was unlikely to pass an instrument into her own uterus, unless prolapse was present, when she might be successful.

(2) Intravaginal injections of various fluids.

(3) Intrauterine injections of fluids, of which soap solution was a favourite. Even scalding water had been used.

(4) Blowing air through a catheter passed into the uterus.

(5) Manipulation of the external os uteri with the hand.

(6) Packing the vagina.

(7) Abdominal massage of the uterus.

(8) The local application of electricity.

(9) Dilatation of the cervix and immediate removal of the products of conception, a method chiefly employed by medical practitioners.

The dangers of instrumental abortion were three—viz., infection, hæmorrhage, and shock.

Infection was favoured by the large raw surface in the uterus and the proximity of large blood-vessels to the placental site. Streptococci and the colon bacillus were the most frequent infecting agents. In fatal cases the course of infection varied greatly. At the one extreme was a rapidly fatal septicæmia with little or no local suppuration, and at the other was a prolonged septicæmia ending in pyæmia. Septic pulmonary infarcts were common. Massive embolism of the pulmonary artery might occur.

Hæmorrhage alone was occasionally responsible for death when the placental site was damaged or the uterus perforated, but it was more frequently associated with septic infection in fatal cases.

Shock often occurred at the moment of passage of an instrument into the uterus and was usually transient, but occasionally instant death occurred. This might also result from the injection of fluid into the uterus.

Discussion.

The PRESIDENT referred particularly to treatment of cases of attempted abortion. Treatment must be prompt and first directed to a thorough cleansing of the whole genital passages. If this proved ineffective there should be no hesitation in opening the abdomen and, if necessary, removing the uterus.—Dr. A. LAPTHORN SMITH endorsed the President's statements, and pointed out that the doctor's first duty was to save the patient and not that of detective. It was always wise in these cases to call in the aid of another practitioner, both for his medical assistance and to avoid any appearance of secrecy. After cleaning the passages he advised the free use of powdered boric in the vagina.—Dr. W. H. WILLCOX congratulated Dr. Spilsbury on his comprehensive paper, and referred to Dr. Spilsbury's unrivalled experience of these cases during the last 15 years. He said that frequently instrumental abortion was aided by ecbolic drugs given either before or after the mechanical interference. He was glad that two important points had been emphasised—viz., that the mere passage of an instrument into the pregnant uterus might cause sudden death. Several instances of this had occurred in recent years. The second point was the extreme rapidity with which septicæmia often occurred, since in many instances septic organisms were directly introduced into the peritoneal cavity.—Dr. J. A. MANSELL MOULLIN agreed with what had been said regarding early treatment. Free drainage of of the infected uterus was imperative, with laparotomy if necessary.—Dr. A. KNYVETT GORDON said that from his experience in the treatment of a large number of cases of puerperal septicæmia he had come to regard the administration of large doses of anti-streptococcic or anti-colon bacillus serum (according to the bacteriology of the case) as the most valuable constitutional remedy we had. At least 100 c.cm. should be given in 2 pints of saline into the subcutaneous tissues. He strongly deprecated the use of vaccines in acute cases. It was wrong in theory and disastrous in practice.—Dr. F. G. LLOYD said that these cases were always unsatisfactory from the practitioner's standpoint. He strongly advocated sharing the responsibility with another practitioner in suspected cases of criminal abortion. He pointed out that any deposition made by the patient could only be taken as evidence if the patient fully appreciated that she was beyond hope of recovery.

Reviews and Notices of Books.

PUBLIC HEALTH AND INSURANCE.

American Addresses by Sir ARTHUR NEWSHOLME, K.C.B., M.D., F.R.C.P. London: P. S. King and Son. Baltimore: The Johns Hopkins Press. 1920. Pp. 270. $2.50.

THE publication of these addresses, delivered in various American cities during 1919 by a man with the extensive experience of Sir Arthur Newsholme, is a matter of interest to a wide circle. In the first lecture, which reviews public health progress in England during the last 50 years, the author refers regretfully to the effect of perfunctory economic teaching, to the neglect of the public health side of the Poor-law organisation, and to the creation of independent local insurance committees, which he considers the greatest blunder of a National Insurance Act, "which was conceived ill-advisedly, had too short a gestation, and suffered a premature and forced delivery." In the second lecture there is a word of warning for eugenic enthusiasts. "Public health embraces some eugenic elements and may comprise more when eugenists have accumulated adequate non-fallacious evidence on which to base valid conclusions." In the same lecture there is also a much-needed defence of representative government and a plea for decentralisation. We cordially agree with Sir Arthur Newsholme that a central authority should not have to concern itself in minutiæ of local administration, but should devote itself to the larger general issues, and to raising the work of all local authorities to the same level of efficiency. Sir Arthur Newsholme has much to say about "the ad hoc vice," the need for the abolition of small and relatively inefficient local authorities and the creation of "complete local Parliaments dealing with all Governmental concerns." A considerable amount of space is also given to a discussion of the great need for an improved medical service, and of how the service should be built up.

The disadvantages of publishing in one volume a number of separate addresses are referred to in the preface; repetitions are unavoidable and are particularly noticeable in the statement of the case against the Insurance Act. Every lecture is of great interest, though perhaps Lecture VII.—The Obstacles to and Ideals of Health Progress—best illustrates the author's grasp of his subject. It seems unnecessary to predict that this volume will be widely read and to suggest that every student of sanitary or social reform will act wisely in making a careful study of its pages.

MANUAL OF MEDICAL JURISPRUDENCE AND TOXICOLOGY.

Fourth edition. BY W. G. AITCHISON ROBERTSON, M.D., F.R.C.P.E., F.R.S.E., Lecturer on Medical Jurisprudence and Public Health, School of Medicine, Royal College of Surgeons, Edinburgh. London: A. and C. Black. 1921. Pp. 414. 12*s.* 6*d.*

THAT Dr. Aitchison Robertson's manual should have gone through four editions since 1908 is alone proof of its recognised usefulness to students studying for examinations. In earlier editions public health has been included with medical jurisprudence and toxicology, but now it has been found more convenient to deal with public health separately. As it stands, the volume on medical jurisprudence and toxicology is packed with valuable matter in a condensed form. The author disclaims any intention to do more than instruct students without competing with the ampler text-books provided for practitioners and lawyers. In the circumstances it is natural that he should not cite authorities for all the varied information that he gives. However, for a writer who deals with legal topics, reference to authorities is a useful check. For example, Dr. Aitchison Robertson goes rather far in saying that when a defence of insanity is raised at the trial of a criminal charge the test is the power of the accused to control his actions. So far as England is concerned it is hardly true to say that what is known as the Rule in M'Naughton's case is obsolete. Many medical men have argued that it is capable of improvement, and juries have not always been induced to apply it strictly, but the change here, at any rate, has not gone further than that.

ANXIETY HYSTERIA.

Modern Views on Some Neuroses. By C. H. L. RIXON, M.D., M.R.C.S., Senior Neurologist, Ministry of Pensions Neurological Hospital, Exeter; and D. MATTHEW, M.C., M.B., Ch.B., Neurologist to the same hospital. With a Foreword by Colonel Sir A. LISLE WEBB, K.B.E., C.B., C.M.G., &c., Director-General of Medical Services, Ministry of Pensions. London: H. K. Lewis and Co. 1920. Pp. 121. 4*s.* 6*d.*

THE authors have written a little monograph on anxiety and conversion hysteria as seen by them in a wide experience of the neuroses of war. The book follows more or less didactically the common lines of psychopathology, symptomatology, diagnosis, and treatment, and if it contains no striking novelties (not, perhaps, that such are now to be expected) it embodies much sound and useful teaching. In particular, the diagrams given in the first of the above-mentioned sections are eminently calculated to enable the general practitioner to form a better idea than he is otherwise likely to get of the mechanisms concerned in the production of hysterical symptoms—i.e., the mental mechanisms. For while reference is duly made in the text to such physical symptoms as tremor, ocular symptoms, sweating, palpitation, vasomotor and pilomotor symptoms, &c., no attempt is made to explain the physiological mechanism of their production, important though this must obviously be, and no correlation of neuroglandular or neuronal disorder with psychological disorder is envisaged. We are, it is true, told that the vasomotor system is very liable to be unbalanced as the result of the emotional conflict, but in the symptomatology of hysteria there is more than a mere secondary effect on neuronal function of primary psychological disturbance. It is the peculiar nature of the disorders on the physiological level that calls for minute and unprejudiced investigation.

Taken as a whole, nevertheless, and considering the expressed aim of the book to be a guide for the general practitioner dealing with cases of hysteria on medical boards, we are of opinion it serves a useful purpose.

HYPNOTISM.

An Introduction to the Study of Hypnotism, Experimental and Therapeutic. Second edition. By H. E. WINGFIELD, M.A., M.D., B.C. Cantab., Consulting Physician, Royal Hants County Hospital. London: Baillière, Tindall, and Cox. 1920. Pp. 195. 7*s.* 6*d.*

THE second edition of Dr. Wingfield's introduction to the study of hypnotism should go far towards removing the prejudice still lurking in some quarters against the more general use of the procedure as a psychotherapeutic method of service in selected cases. Describing in simple and direct terms his exact technique, Dr. Wingfield substantiates his claim to enduring results in many instances by a series of brief clinical records, the value of which is undoubtedly increased by his candid admission of the limitations of the method and by his expressed unwillingness to hail in hypnotism a panacea for epilepsy, morphinism, dipsomania, stammering, and what not. Owing to the vogue of psycho-analysis as a therapeutic process hypnotism has perhaps somewhat fallen into the background; yet Dr. Wingfield's experience is that in the latter method lies a powerful factor in the unearthing of repressions supposedly accessible only to the former, and since psycho-analysis is in many cases practically an impossibility, more use might certainly be made of hypnotism. For a sane, cautious, and discretionary advocacy of the treatment of neurosis by suggestion with or without actual hypnotisation we can recommend the physician to turn to Dr. Wingfield's book.

NERVES AND THE MAN.

A Popular Psychological and Constructive Study of Nervous Breakdown. By W. CHARLES LOOSMORE, M.A., Brown Scholar at Glasgow University. London: John Murray. 1920. Pp. 234. 6*s*.

WE hope the day is far distant when the medical man will become so knowledgeable from the perpetual imbibition of strictly professional treatises that he will refuse to learn anything from those outside the pale of the Medical Register. As it is, there is, and has always been, a tendency to ignore contributions to therapy emanating from lay sources, doubtless because such are often characterised by one-sided presentation of the particular thesis advocated—a failing, however, not confined to non-professional contributions. The student of functional nervous disease, remembering that he must treat the whole man—body, soul, and spirit—and conscious that a knowledge of human nature is worth tons of text-book lore, will hail a kindred mind and appreciate innumerable therapeutic hints, no less valuable because not couched in technical language, as revealed in Mr. Loosmore's "Nerves and the Man." The management of the neuropathic individual is as onerous as his treatment, and none can manage others to whom his own mental trends, intellectual and affective, are as a sealed book. For ever treating others, the physician is too often forgetful of the old adage "Know thyself." A useful corrective is to be found in the slender volume under review, which we have perused with pleasure and profit no less for its literary garb and style than for the thread of sound common sense interwoven throughout. At critical periods in a man's life certain phrases, certain thoughts couched in an epigrammatic form, it may be, have proved often enough precious pegs on which to hang up his troubles, and though possibly Mr. Loosmore's "restful phrases" have more of a religious cast than certain others, the principle is absolutely sound. The reader will find a charm in scanning the pages of this little guide to self-knowledge and in applying to himself the wisdom gleaned from many fields and admirably set out by its author.

ANATOMY OF THE BRAIN AND SPINAL CORD.

Fifth edition. By RYLAND WHITAKER, B.A., M.B. Lond. Edinburgh: E. and S. Livingstone. 1921. Pp. 262. 12*s*. 6*d*.

WE welcome a new issue of a book which has always been a favourite with those who desire more than a purely superficial acquaintance with the intricacies of the central nervous system. This edition has been in part rewritten and rearranged by the author and makes a small volume of description easy to read and follow, with illustrations clear and good, if sometimes rather small. The main portion of the book is descriptive anatomy, and can be heartily recommended to the student. The last chapter deals shortly with development and is more in accordance with common form; here we would point out that the infundibulum is not to be described with strict accuracy as developing from the telencephalon. A slip of such sort, however, does not detract from the value of the book as an exposition of central nervous anatomy and arrangement, and it is from this point of view that we offer it welcome.

TEXT-BOOK OF EMBRYOLOGY.

Third edition, enlarged. By (the late) C. W. PRENTISS and LESLIE B. AREY. London and Philadelphia: W. B. Saunders Company. 1920. With 388 illustrations. Pp. 412. 27*s*. 6*d*.

THE Embryology of the late Professor Prentiss was a well-known book which, after his untimely death, passed into other hands for its second and third editions: in these hands it has more than retained its position among students in America. It deals with the development of the human, pig, and chick embryos from the laboratory and student's point of view, and gives clear and well-illustrated accounts of the processes. But, as we have had occasion to point out with reference to several works emanating from the other side of the Atlantic, the foundation is practically altogether German, and it may be said that embryology in England has gone beyond the level adopted in these works. We may add that one of the very few references in this book to English work is to the demonstration of the maturing human ovum by Professor A. Thomson, which is regarded as hardly conclusive. This is of course a matter of opinion, but those who had the good fortune to be present when Professor Thomson demonstrated his specimens will hardly agree with it. We say this in no spirit of rancour—the book is an excellent one, so far as it goes, but we do not consider that it goes far enough for English students. A meed of congratulation is due to the publishers for the way in which the volume is turned out.

PHYSICAL CHEMISTRY.

Praktikum der Physikalischen Chemie insbesondere der Kolloid-chemie. Für Mediziner und Biologen. Von Prof. Dr. med. LEONOR MICHAELIS. Berlin: Julius Springer. 1921. Mit 32 Text-abbildungen. Pp. vii. + 160. M.26.

THIS book contains a description of over 70 experiments in physical chemistry which Professor Michaelis has devised for his numerous pupils; they have been gradually evolved during the course of many years, partly in conjunction with his colleague, Professor P. Rona. The names of these authors are well known to all biochemists, and we have pleasure in recommending this volume to our readers, as the experiments will be found of value alike by the beginner and by the more advanced worker. Before each group of experiments there is a short explanatory section stating upon what principles the method depends or what is its importance in biology. The experiments are arranged methodically, though not always in accordance with the physical subject-matter. Thus, they begin with the simple "series" experiment of determining rennin and pepsin, and lead on, through colloidal precipitation, determination of hydrogen-ion concentration by means of indicators, surface-tension, diffusion, adsorption, to the measurement of electrical conductivity and electro-motive force. Every experiment is clearly and neatly described, the more complicated being greatly assisted by the many excellent diagrams of apparatus.

PHYSIOLOGY OF PROTEIN METABOLISM.

By E. P. CATHCART, M.D., D.Sc., F.R.S. (Monographs on Biochemistry.) London: Longmans, Green, and Co. 1921. Pp. 176. 12*s*. 6*d*.

THIS monograph, like all others in this excellent series, is an example of the best method of crystallising out what is really known from what is surmised. It deals with the digestion, absorption, and subsequent history of protein in relation to the economy of the body as a whole, and in relation to the physiology of starvation and work. Though some overlapping with Dr. R. H. A. Plimmer's monograph on the "Chemistry of the Proteins" is inevitable, the balance between the purely chemical and the biological is well preserved. The subject is one of peculiar intricacy. In its broadest outlines protein metabolism can no doubt be presented in an apparently simple and conclusive manner, but when we come to look a little deeply the simplicity vanishes. It is unfortunately true that few but professional physiologists are likely to appreciate this volume to the full, but the fault for this does not lie with its author. Even the chemistry of the proteins is a clear and well-explored domain when compared with the physiology of protein metabolism. But it must not be imagined that the subject is a dull one, or that Professor Cathcart has not dealt with it in a satisfactory way. Indeed, his own researches in this field qualify him to write with that clearness and vitality which pertain only to first-hand knowledge. Despite the vast amount of work which has been done since the days of Voit, there is as yet no unanimity of opinion on any of the fundamental physiological questions of protein metabolism—for example, on the minimum protein requirement or the relations of protein to the energy needs of the body. The perusal of the present volume leaves us with a stronger impression than ever that we have now much information but little knowledge on the subject; doubts, unverified hypotheses, and unsolved problems cropping up on almost every page. An important object of these monographs is to consolidate our advances and to gain observation posts for future work. The author has admirably accomplished both of these aims. The large and up-to-date bibliography (25 pages) is a useful feature, but it should be pointed out that some at least of the references in the text are not to be found therein. One of these is to work done by Mrs. G. D. Cathcart.

SIX PAPERS BY LORD LISTER.

With a Short Biography and Explanatory Notes by Sir RICKMAN J. GODLEE, Bart. (Medical Classics Series.) London: John Bale, Sons, and Danielsson, Ltd. 1921. Pp. viii. + 194. 10*s.*

THIS little volume is one of a series dealing with "some of the most epoch-making contributions to medical science," published under the general editorship of Dr. Charles Singer. It is intended to follow this volume with others treating of Paré, Laennec, Auenbrugger, Hippocrates, and Galen. It is eminently fitting that the work of a man whose researches revolutionised surgery should lead the series, and we must congratulate Sir Rickman Godlee upon his illustrative selection and also for his biography, though there are naturally, as Sir Rickman Godlee confesses, many regrettable gaps. However, we have papers upon the Early Stages of Inflammation, on Anæsthetics, on a New Method of Treating Compound Fractures, a Demonstration of Antiseptic Surgery, on the Nature of Fermentation, and an address on the Present Position (1890) of Antiseptic Surgery, delivered before the International Medical Congress at Berlin. Of these papers the two upon Compound Fractures and upon Fermentation are perhaps the most interesting, and give a very good picture of Lister's patient way of working and of the honesty in which he always set forth his failures together with his successes; it is interesting, too, to compare the paper upon Fermentation (1877) with Tyndall's treatment of the same subject in 1876.[1] There is, by the way, what seems to us a somewhat misleading statement in a note (p. 95) to a passage in the paper on compound fractures—"*Carbolic acid is almost absolutely insoluble in water*," for the crystalline purified variety which is mentioned in the note is soluble in 1-14 of water at 56° F.

The collected edition of Lord Lister's papers is expensive and the selection now before us will help many who have neither the time nor the opportunity to read the full collection, to realise what manner of man Lister was, and how great is the debt which suffering humanity owes to his patient studies.

CHEMICAL PATHOLOGY.

Fourth edition. By H. GIDEON WELLS. London and Philadelphia: W. B. Saunders Company. 1920. Pp. 695. 35*s.*

THIS text-book has now reached its fourth edition, and has been revised and additional new matter incorporated without any serious increase in size. Dr. Wells gives a review of general pathology from the standpoint of the chemical processes involved. The importance of a knowledge of the chemical changes induced in various morbid anatomical states cannot be too fully emphasised. We know of no other book which really attempts to describe these changes with such a thorough review of the literature. For example, the well-known amyloid degeneration is described, including its chemistry, and the views which have been put forward as to its origin. If one refers to the book for information on such subjects as calcification, fat necrosis, the composition of exudates and transudates, or of gall-stones, a good account will be found, with abundant references to the literature.

The book can be recommended not only to the pathologist but to the student who is desirous of obtaining information on chemical pathology, and thus bridging the gap between his knowledge of chemical physiology and general pathology. It can also be recommended to the clinician, since in it he will find abundant information on the present state of our knowledge of the chemical changes induced in disease. The chapter on anaphylaxis is good; a difficult subject is clearly dealt with, modern views being discussed. The chapter on the chemistry of growth and repair, including as it does an excellent summary of our knowledge of deficiency diseases, and the part played by vitamines is also worthy of special mention. In passing we observe that Dr. Wells is inclined to regard pellagra as a deficiency disease, and it is therefore included in this chapter. The chapter on pathological pigmentation deals with the chemistry of pigments, a subject of absorbing interest, and the relations of the various pigments are here described. A good account of melanin and lipochromes will also be found in this chapter, as well as a description of blood pigments. The so-called toxæmias are exhaustively considered from the chemical point of view, and the physician will obtain much valuable information from a perusal of the book, particularly with regard to uræmia, the toxæmias of pregnancy, and acidosis and ketosis. The difficult and complex problem of intestinal toxæmia has attracted considerable attention amongst medical men; a large number of diseases have been ascribed thereto, and it is of interest that the advance of chemical knowledge tends to minimise the importance of this as a cause of disease.

Dr. Wells has produced a really excellent work which can be recommended to all interested in the subject of chemistry as applied to medicine, and for the mass of readable information and the copious references to the literature contained therein.

BOOKS FOR NURSES.

1. *Medicine for Nurses.* By JOHN HENDERSON, M.D., Ch.B., F.R.F.P.S. Glasg. London: Edward Arnold. 1921. Pp. 263. 8*s.* 6*d.*

ALTHOUGH Dr. Henderson's book should prove of undoubted value to nurse-students who prefer to study special books on the special departments of nursing, it cannot be said that it is a particularly useful addition to nursing literature, and the information it offers in no way excels that contained in any comprehensive textbook on general nursing. Dr. Henderson explains that care has been taken to select only essential material, but it must be realised that the finesse of nursing depends largely upon a full understanding of the details which underlie good technique, and although the nursing and treatment are given in conjunction with each disease, one could wish for a more graphic description of nursing methods. The subject-matter is well arranged, and specially commendable is the short introduction on surface anatomy to each class of disease. The book can be recommended to students who are under the close supervision of a ward sister or sister-tutor responsible for the correct application of the treatment prescribed.

2. *Bandages and Bandaging for Nurses.* By M. CORDELIA COWAN. London and Philadelphia: W. B. Saunders Company. 1920. With 189 illustrations. Pp. 177. 10*s.* 6*d.*

THE excellent illustrations which make up the greater part of Miss Cowan's book almost convince us that it may be possible to achieve success in the difficult art of bandaging without the aid of a demonstrator. So realistic are the reproductions of the methods employed that each step may be closely followed until the required result is reached. We congratulate Miss Cowan upon the concise and attractive form in which she has presented her subject, and regret only that the present price of her book may prevent many English student-nurses from purchasing it.

---

[1] Fragments of Science, vol. ii., p. 251.

THE MOTHER AND THE INFANT.

By EDITH V. ECKHARD. London: G. Bell and Sons, Ltd. 1921. Pp. 256. 6*s.* net.

THIS is a new volume of the Social Service Library, under the general editorship of C. R. Attlee. Miss Eckhard, who is a tutor in the Ratan Tata department of Social Science in the University of London, in conjunction with which the books in this series are published, has contributed an account of the aims and activities of the child-welfare movement, at least as far as these concern the child up to school age. Miss Eckhard points out how far the scope of voluntary organisations is enlarged by the growing activities of the State, and lays stress on the many ways in which a closer coöperation between these public and private bodies can be made effective. The main interest and value of the work, indeed, lie in the constructive and very practical suggestions scattered throughout its pages; and, though for many of the problems raised the author frankly acknowledges that there is no one solution, there is nothing vague or nebulous in the way in which the facts and the difficulties alike are faced.

The opening portion of the book describes the need for child-welfare work, and the growth of the movement from small and humble beginnings, the succeeding chapters dealing with the expectant mother, child-welfare centres, creches, day nurseries, and other organisations. There is a useful chapter on Workers and Training, in which is criticised the inadequate training, both theoretical and practical, allowed by the two years' course for health visitors; it must, indeed, be difficult to plan the time-tables in view of the wide range of subjects to be covered.

The book, as a whole, bears evidence of careful thought, and is one which will repay study by the social science worker of to-day.

THE LITERARY YEAR-BOOK, 1921.

London: Routledge and Sons, Ltd. Liverpool: Editorial Offices, 67, Dale-street. 8*s.* 6*d.*

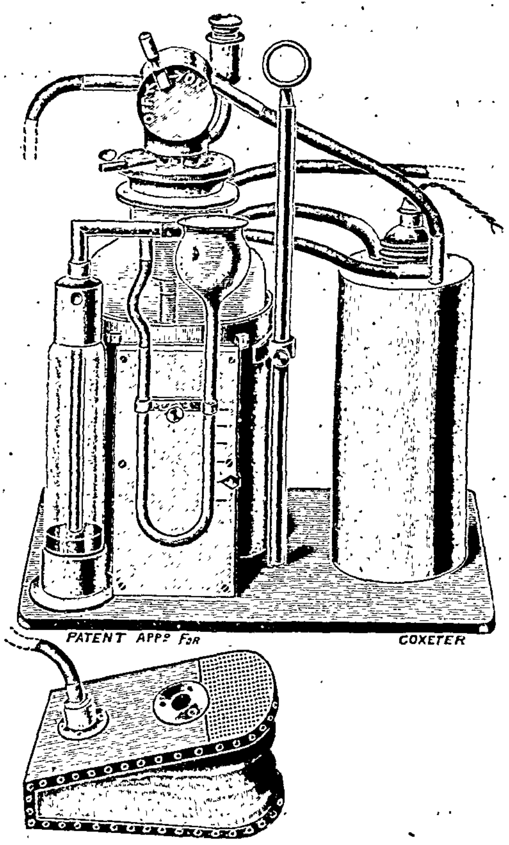
IN amount and arrangement of matter this issue is the best which has appeared. The Directory of Authors and Journalists, with a note on pseudonyms, occupies some 300 pages, and quantity of output must in such a work of reference determine to a considerable extent the amount of space allotted to each writer rather than his or her literary position. Mr. Thomas Hardy, Miss Marie Corelli, Mrs. Irene Osgood, and "Rita" tie with 15 lines apiece, and Sir Hall Caine and Mr. John Galsworthy with 14. Mr. Bernard Shaw does not detail his work, and fills only nine lines, while Sir Harry Johnston and Mr. E. V. Lucas each occupy 22. There are notable omissions, but it is impossible that this should be otherwise; everyone who writes is not an author, and when he may be said to become one defies definition. In a sense medicine has not, perhaps, been adequately noticed—neither Sir Clifford Allbutt nor Sir Almroth Wright are to be found in the directory, though the letters after the Poet Laureate's name serve to remind us that he is a medical man. The medical author, however, is an excellent example of the writer whose literary output is usually subservient to his proper calling. Our sympathies go out to the compiler of this list, who can have no arbitrary rules to guide him as to exclusion or inclusion.

Amongst the many features of general literary interest is a useful chapter on "Literary Property" contributed by Mr. G. H. Thring, the Secretary and Solicitor to the Society of Authors. This article embodies the experience and practice of years, and should have the desirable result of inspiring all who would enter into business arrangements with regard to the publication of their works to seek the advice of this Society. The chapters headed "Thoughts on Selling MSS.," "The Author as a Business Man," and "Some Hints for Contributors" are all valuable.

New Inventions.

A SIMPLE AND EFFICIENT INTRATRACHEAL ETHER APPARATUS.

THIS apparatus is simple in construction and gives a constant vapour of any strength at an even temperature. It may be worked with a foot-bellows, rotary pump, compressed air or oxygen as desired. As will be seen from the illustration the apparatus consists of: A light and specially constructed foot-bellows; a bottle to contain ether fitted with a new type of regulating valve; a water bath; a safety valve and manometer; and an electric or hot water heater. A filter packed lightly with cotton-wool is placed in the course of the tube leading from the bellows to the bottle which contains the ether.



The upper lever of the regulating valve diverts the air from the bellows *over* the surface of the ether or completely shuts it off. I have used this apparatus in a large number of cases of all sorts—e.g., removal of neoplasms of the neck, removal of tongue, upper jaw, &c., and it has proved itself to be efficient. The apparatus can be equally well used for the administration of intratracheal chloroform.

Messrs. Coxeter and Son, 171, Pancras-road, N.W. 1, to whom I am indebted for many helpful suggestions with regard to mechanical difficulties and also for making a light and efficient pair of foot-bellows, are the wholesale makers of the apparatus.

A. W. MATTHEW, M.R.C.S., L.R.C.P. Lond.,
London, W. Anæsthetist to St. Mary's Hospital.

THE King has granted unrestricted permission to Mr. A. A. Miller, L.R.C.P. Lond., M.R.C.S., to wear the Cross of the Chevalier of the Legion of Honour, conferred upon him by the President of the French Republic in recognition of services to the French sick and wounded in the late war.

FRENCH SUPPLEMENT TO THE LANCET

Under the Editorial Direction of

Professor CHARLES ACHARD,
PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PARIS.

AND

Dr. CHARLES FLANDIN, D.S.O.,
CHEF DE CLINIQUE A LA FACULTÉ DE PARIS.

OCULAR TRAUMATISM AND MENINGITIS.[1]

BY PROFESSOR F. DE LAPERSONNE.

THE following is a summarised account of a case of acute meningitis following an infected wound of the eye, seen at the Ophthalmological Clinic of the Hôtel-Dieu, Paris.

Patient, a boy, aged 13, was wounded in the right eye by broken glass on Oct. 9th, 1920. An oculist, consulted on the 11th, reported a penetrating wound of the cornea, with hypopyon. On the 19th the patient was sent to the Hôtel-Dieu and admitted as an urgent case; upon examination we found panophthalmia with yellowish cornea and chemosis. Movements of eyeball limited; temperature 38° C.; headache and excitement. Exenteration was immediately performed, with local anæsthesia, by Dr. Velter, *chef de clinique*. Complete curettage, followed by thermo-cauterisation of the orbit, brought away the whole of the membrane and masses of purulent matter. On the same day the temperature rose and remained at 40° C. until the following day. On the 21st it fell to 37° C., and 3 c.cm. of Delbet's serum was injected. On the 22nd temperature again rose; there was stiffness of the nape of the neck, and Kernig's sign, but no vomiting or headache. Lumbar puncture gave a doubtful liquid. An intravenous injection of 20 c.cm. of electrargol was given.

On the 23rd the nervous symptoms were less evident, the patient was calmer and more sane; temperature was 38·2° C. On the 24th further injections of Delbet's serum and electrargol were given. On the 25th the meningeal symptoms were accentuated; the occipital headache was intense, with great excitement, nocturnal cries, Kernig's sign; temperature 40·2° C., pulse uncountable. Pupil of unaffected (left) eye dilated; papillary stasis present. Another lumbar puncture was made. Injections of electrargol and Delbet's serum were continued; on the 29th an injection of antimeningococcal serum was given. Lumbar puncture gave a liquid distinctly cloudy and hypertensive. The temperature remained above 39° C.; the patient died on Oct. 31st, three weeks after the injury and 12 days after the operation.

Examination of cerebro-spinal fluid.—The first and second lumbar punctures showed abundant polynucleosis, but direct examination revealed no bacterial elements. The third puncture showed considerable polynucleosis with numerous pneumococci, presenting their characteristic aspect of diplococci encapsuled and Gram-positive. There was no question of meningococci, which have a different morphological character and are Gram-negative. Cultures from the fluid obtained by anterior puncture gave pure pneumococci.

Autopsy.—The exenterated ocular cavity was perfectly empty, there being no choroidal debris. The orbit contained neither purulent infiltration nor any foreign body. A generalised meningeal congestion was observed, with hæmorrhagic pachymeningitic plaques. The arachnoid cavities were filled with a muco-purulent fibrinous mass. The base of the skull was especially involved; the median fossa was covered with thick greenish-yellow pus, which had spread over the entire anterior arachnoid membrane, and traces of which had reached the anterior fossa and even the cerebellar fossa. The sinuses of the dura mater were intact.

Simple and Complicated Injuries of the Eye.

Meningeal affections following ocular or oculo-orbital injuries are rare, but very serious. War ophthalmology has given relatively numerous examples of traumatic meningo-encephalitis caused by oculo-orbital injury. Not only the eye was involved; the vulnerant agent had produced an oculo-orbital wound, with direct fracture of the base of the skull in the anterior fossa and with discharge of cerebro-spinal fluid. We have observed 12 cases of meningo-encephalitis amongst 1500 wounded treated in the ophthalmological department of the Hôtel-Dieu, and were able to distinguish the following four varieties.

1. Very acute form. *The patients reached us very* quickly, but were already in a manifestly meningitic condition. They rapidly became delirious or comatose and died in less than 48 hours.

2. Ordinary form, with stiffness *of back of neck*, Kernig's sign, excitement, and fever. Cerebro-spinal fluid cloudy; death within ten days.

3. Slow form, lasting three weeks, with very irregular thermic curve, and periods of excitement and quiet. The cerebro-spinal fluid filtered more or less intermittently through the wound; its issue sometimes coincided with a partial remission of symptoms. This fluid, clear or mixed with pus or blood, had an ammoniacal odour. The condition produces progressive enfeeblement and terminates in death.

4. Form admitting of cure. Certain patients were cured in spite of very grave injuries. In the case of one of our blinded men a bullet had destroyed the contents of both orbits and the root of the nose. Cerebro-spinal fluid flowed from this large wound, in which the cerebral pulsation was visible. After a period of great danger the patient developed mental disturbances for some months. We have lately seen him in good health.

Simple penetrating wounds limited to the eyeball can also produce meningeal disturbance. Several observations have been published upon this subject. In 1897 I presented to the Société Française d'Ophtalmologie the following summarised account of a case resembling in every way that reported at the beginning of this paper.

A child, aged 12, was wounded in the cornea by a blow with a pair of scissors. On the fifth day very painful iridocyclitis was observed, with headache and excitement. Classical enucleation was performed on the sixth day; incision of the eyeball revealed a purulent iridocyclitis with involvement of the vitreum. The child remained in an excited condition and headache persisted. The third day after operation the temperature rose to 40° C., with severe headache, vomiting, delirium, and stiffness of the nucha. Death occurred on the tenth day after intervention.

Autopsy.—Suppurating meningitis was revealed, only slight at the convexity, but forming at the base a thick greenish yellow exudate, extending from the medulla oblongata to the optic chiasma. Bacteriological examination demonstrated the existence of pneumococci, with no associated organisms, in the meningeal pus and in the sheath of the optic nerve. The sinuses of the dura mater presented no alteration.

Kalt has published accounts of two cases of pneumococcal meningitis following operation (one a child suffering from orbital sarcoma with corneal ulceration, the other a man of 60, enucleated for purulent iridocyclitis). These conditions must be distinguished from thrombo-phlebitis of the orbital veins and of the cavernous sinus. We have lately observed the following case:—

On Nov. 3rd a man, aged 40, was admitted to the Hôtel-Dieu as an urgent case, with a temperature of 40·6° C. and delirium. He presented, on the same side as iridocyclitis of long standing, orbital cellulitis with palpebral œdema, exophthalmia, and papillary stasis. After 48 hours the same symptoms were observed on the other side. Thrombo-phlebitis of the orbital veins and of the cavernous sinus had attacked the other side by way of the coronary sinus. The cerebro-spinal fluid showed abundant polynucleosis. The patient died four days after his admission to hospital.

Pathogenic Agency of the Pneumococcus.

The pneumococcus is the pathogenic agent of meningitis following infected wounds of the eye. Since 1897, at the Société Française d'Ophtalmologie—i.e., in the thesis of my pupil Painblan (Lille, 1897), and in a lecture delivered at the Hôtel-Dieu (*Presse Médicale*, 1901)—I have insisted on the part played in these complications by the pneumococcus. In Germany, a year before my first communication—i.e., in 1896—Zimmermann had reported, in a case of meningitis following enucleation, the presence of "undifferentiated cocci." The pneumococcus, however, has been recognised since Talamon and Fraenkel. My colleague, Calmette, Director of the Pasteur Institute at Lille, and I attempted at that time to produce the same phenomena experimentally.

---

[1] A lecture delivered at the Ophthalmological Clinic, Hôtel-Dieu, Paris.

Our results with rabbits were as follows: (1) Section of optic nerve; injection into sheath of nerve of a drop of only slightly virulent pneumococcal culture; death, due to generalised infection, in 10 days. (2) Inoculation into anterior chamber with a strong pneumococcal culture; death in two days, due to pneumococcal toxæmia.

In these two cases we did not find orbital or meningeal suppuration, but we proved the presence of the pneumococcus in the optic nerve-sheath, at the level of the optic chiasm, and at the base of the brain.

The pneumococcus often exists as a saprophyte in the conjunctival culs-de-sac and in the lacrymatory canals without causing the slightest inflammation; but it is also often pathogenic, producing conjunctivitis of the new-born and corneal ulcer with hypopyon, and when penetrating injury of the eye takes place it frequently begins to cultivate, and may produce meningitis. Our two observations concern children of 12 and 13 years of age, but analogous adult cases have been reported. Must we assume that a process of anaphylaxis takes place—that after a former pneumococcal infection the system is specially sensitised for the pneumococcus? In any case this micro-organism is a redoubtable enemy.

Method of Treatment.

Experiments in vitro show that certain antiseptic solutions (the mercuric salts, such as sublimate, for instance) do not penetrate the enveloping capsule of the pneumococcus. Lavages, and even subconjunctival injections, of sublimate or cyanide probably have no action, since ocular infection depends upon the pneumococcus. Alkaline substances dissolve the capsule and prevent the pneumococcus culture from spreading. Since 1897 I have used hyperchlorite of calcium, but I have had to stop using it, because it sets up irritation of the conjunctiva. The hypochlorites again came into use during the war (Carrel's method, with Dakin's fluid), and I myself in 1917 advised the employment of chloramine in 1 per cent. solution, for oculo-orbital war injuries.

In the presence of a penetrating injury of eyeball or orbit success depends essentially on rapidity of diagnosis and treatment. The patient should be carefully and quickly examined with use of radiography or radioscopy. Intervention should follow rapidly—less than 24 hours after the injury. My pupils, Duverger and Velter, in their work "Ophtalmologie de Guerre," have detailed the rules of rapid treatment, which treatment is essentially conservative. But in the presence of an acknowledged panophthalmia, all delay is dangerous; here the eye is painful, definitely lost for purposes of sight, and likely to induce grave complications. The surgeon must choose between enucleation and exenteration. In 1884, de Graefe, after the death of two of his cases of panophthalmia, insisted upon simple evisceration in preference to enucleation. In 1889, an interesting discussion on this question was held at the Société Française d'Ophtalmologie; Panas and Gayer preferred enucleation, but the former afterwards adopted exenteration with the cautery, which I advocated in 1892 for all cases of panophthalmia.

Exenteration has this great advantage over enucleation: the sheath of the optic nerve is not thereby opened and infected. At the International Congress of Medicine held in Paris in 1900 Pfluger, Snellen, de Schweinitz, and Swanzy presented reports on "Enucleation and suggested operations to replace it." Agreement between them was not complete. Moreover, the total statistics from 1861 to 1896 of Moorfields Hospital showed seven cases of death in 6876 enucleations. It must be noted, however, that these 6876 cases were not all of panophthalmia, and that the seven deaths all followed panophthalmia. In 1908 Albert Terson, in a report on the Treatment of Wounds of the Eye, declared that "exenteration with the cautery as advised by Lapersonne should be accepted as the least dangerous and most efficacious operation against panophthalmia." Antonelli made certain reservations in connexion with sympathetic ophthalmia, but sympathetic ophthalmia is not to be feared in panophthalmia; what is to be feared is plastic iridocyclitis. In 1912 Jacqueau, of Lyons, recorded a case of panophthalmia consequent upon a penetrating wound, in which enucleation was followed by death.

Conclusion.

At the present time exenteration with the cautery is practised by the majority of ophthalmologists. Consideration of the case recorded at the outset of this lecture does not point to contra-indications, for it is clear that the meningeal affections existed before the operation.

I am convinced that exenteration with the cautery is demanded by the indications I have detailed. It is the only treatment for acute panophthalmia following a penetrating accidental or surgical wound of the eye, with infiltration of Tenon's capsule, chemosis, and threatened orbital cellulitis. But if fever, headache, and other symptoms are already in evidence, the prognosis must clearly be made with reservations as to meningeal complication.

CORNEAL ANÆSTHESIA

INDUCED BY LESIONS OF THE TRIGEMINUS.

BY CH. COUTELA,
OPHTHALMOLOGIST TO THE PARIS HOSPITALS;
AND
A. MONBRUN,
HEAD OF THE OPHTHALMOLOGICAL LABORATORY, HÔTEL-DIEU, PARIS.

CORNEAL anæsthesia may exist in an isolated condition and may pass unobserved, but more often it forms part of a neuro-ocular syndrome—neuro-paralytic keratitis, ablation of the Gasserian ganglion, fracture of the base of the skull, ophthalmic herpes, neuralgic herpes of the cornea, or kerato-malacia. It is nearly always connected with a lesion of the Gasserian ganglion. The ophthalmic nerve, its nasal branch, the ophthalmic ganglion, or the ciliary nerves can, however, be directly reached. Sometimes it is connected with a lesion of the root of the trigeminus, or of a protuberant lesion (alternate hemianæsthesia), or of a cerebral lesion (hemianæsthesia).

Isolated Corneal Anæsthesia.

This condition may exist unobserved, but if a minimal corneal injury takes place or an operation on the eye is performed it may be the beginning of neuro-paralytic keratitis. In order to avoid serious complications it is well to pay strict attention to the sensibility of the cornea. We shall shortly refer to a case of fracture of the skull in which a very slight traumatic conjunctival keratitis ended in necrosis of the cornea with panophthalmia. The corneal anæsthesia had not been dealt with sufficiently early.

Corneal Anæsthesia and Operation for Cataract.

In four of our cases operated upon for cataract complications developed; and only the accident of these complications enabled us to discover corneal anæsthesia in the eye operated upon, an anæsthesia also existing in the other eye. A brief record of these four cases follows:—

CASE 1.—Complete bilateral cataract; aged 88. Nothing to report. On Jan. 23rd, 1920, extraction of the cataract of the left eye, with iridectomy and suture of the cornea. Cicatrisation of the corneal incision only took place after five weeks; no pain. No other complications, except an intense oblique astigmatism, reducing vision to 6/60.

CASE 2.—Complete bilateral cataract. Nothing to report. Right eye: extraction with iridectomy, without suture; incomplete coaptation of corneal incision for more than three weeks. Interstitial opacification of superior part of cornea.

CASE 3.—Female, aged 58, alcoholic. Lacrymal ducts impermeable, but not infected. Complete bilateral cataract. On Dec. 6th, 1919, preparatory iridectomy of right eye. On July 3rd, 1920, extraction of cataract and suture of cornea.

incomplete coaptation of corneal incision. Iridocyclitis with hypopyon, atrophy of eyeball. No pain. Corneal cicatrisation *only complete after six weeks.*

CASE 4.—Female, aged 64. Left eye operated upon for cataract in 1916, with no complications. Right eye: complete cataract. Former involuntary lacrymation, but the injection was well taken, and there was no conjunctival reaction. On Oct. 7th, 1920, extraction of the cataract with iridectomy and suture of cornea; incomplete coaptation of incision. Iridocyclitis without pain, hypopyon, then panophthalmia, necessitating exenteration.

There is no reason to attribute the corneal anæsthesia to our intervention. In his thesis on "Corneal Sensibility" (Paris, 1908) Cerise showed that "it is always on the cicatrice itself that sensibility returns in the first place," and that the corneal portion rapidly regains its innervation. In our four cases complete and persistent anæsthesia was present extending over the whole cornea not only of the eye operated upon but also of the other eye. This insensibility was evidently present before the operation, and caused delay of cicatrisation. The first case had no troublesome sequel; the second was complicated by corneal opacity. In the third and fourth cases incomplete cicatrisation of the incision facilitated septic endo-ocular complications (atrophic iridocyclitis, panophthalmia) due to the defective condition of the lacrymal ducts. To sum up—before operating on cataract it seems to us of value to complete the examination of the condition by testing the corneal sensibility.

Neuro-paralytic Keratitis and Extension of Anæsthesia into the Trigeminal Tract.

It is evident that anæsthesia of the whole trigeminal tract can only be induced by a Gasserian or retro-Gasserian affection. When the anæsthesia only affects the tract of the ophthalmic nerve the lesion is seated behind the orbit or at the level of the Gasserian ganglion. We have observed in our present work under Professor F. de Lapersonne a neuro-paralytic keratitis with anæsthesia of the ophthalmic nerve and hemicrania, very probably connected with an endocranial neoformation of the region of the Gasserian ganglion. The anæsthesia is often limited to the cornea and to the conjunctiva, and more often still to the conjunctiva alone. The lesion may be in front of the Gasserian ganglion, and sometimes at the level of the ciliary nerves themselves (orbital affection), but almost always it is a lesion of the Gasserian ganglion itself. And in that case, how can we explain affection of corneal sensibility when cutaneous sensibility remains unaffected? It would be interesting to know if this greater vulnerability of the fibres supplying the cornea is due to the disposition of their course across the Gasserian tract. Another hypothesis appears equally admissible: the very special sensibility of the cornea would be more easily modified than that of the skin.

The skin reacts in three forms of sensibility, unlike the cornea. Corneal sensibility to pain is very great; corneal sensibility to contact, denied by the majority of writers, is ill-defined; it requires separation of the points of Weber's compass by more than 5 mm. Corneal sensibility to heat is a disputed question; a current of hot air produces a sensation of cold. However it may be, neuro-paralytic keratitis is oftenest induced by a lesion of the Gasserian ganglion, even when the cutaneous sensibility of the trigeminus is intact.

Neuro-Paralytic Keratitis and the Surgery of the Gasserian Ganglion.

Everyone is aware of the gravity of neuro-paralytic keratitis following resection of the ganglion. To avoid this dangerous complication, certain writers have advised the substitution for this operation of retro-Gasserian section of the trigeminus. For Sicard[1] "section of the root, whilst leading to cure of neuralgia, gives shelter to neuro-paralytic complications." We have, however, just observed a case of neuro-paralytic keratitis following retro-Gasserian neurotomy.

CASE 5.—Female, aged 36, who had suffered for 12 years from trigeminal neuralgia, resisting all treatment. On August 2nd, 1920, Dr. de Martel performed retro-Gasserian neurotomy on her; anæsthesia of cornea and conjunctiva and of the trigeminal tract. Two months after the operation neuro-paralytic keratitis developed with ulceration of the nasal membrane and of the wing of the nostril. Tarsorrhaphy arrested the evolution of the corneal ulceration, and the latter disappeared, leaving several opacities. Absolute corneal anæsthesia persisted.

Neuro-paralytic Keratitis and Traumatism of the Skull.

In the presence of cranial traumatism corneal anæsthesia is a symptom to be looked for. It indicates a lesion of the base and makes it possible to avoid ocular complications.

CASE 6.—Male, wounded Nov. 3rd, 1917, by several fragments of shell. Wounds of limbs and "non-penetrating injury of the left temporal region. Shell splinter extracted from the soft portion"; ordinary traumatic kerato-conjunctivitis, with slight epithelial erosion of the cornea. On Nov. 13th a vast central ulcer was observed, with total corneal anæsthesia and hypopyon; no pain. On the 26th panophthalmia; exenteration. To sum up—a radiating fracture of base of skull, with probable involvement of Gasserian ganglion. If corneal anæsthesia had been discovered in time tarsorrhaphy would, perhaps, have preserved the eye.

Neuro-paralytic Keratitis and Meningeal Reactions.

All bony, meningeal or encephalic lesions involving the Gasserian region can induce neuro-paralytic meningitis. Syphilis occupies the chief place in this ætiology. But it must be realised that the meningeal reactions so frequently observed during certain general or epidemic affections may be accompanied by corneal anæsthesia with neuro-paralytic complications.

Neuro-paralytic Influenzal Keratitis.

During the 1918–1919 epidemic we observed 21 cases of neuro-paralytic keratitis in patients suffering from influenza.[2] This manifestation was accompanied by pains in the trigeminal tract on the same side, with headache. In cases where lumbar puncture was performed we found very distinct albuminosis and lymphocytosis.

Corneal lesions have a polycyclic contour, as in corneal herpes. One of our cases presented numerous vesicles, analogous to those of herpes zoster, on the upper eyelid.

Keratomalacia.

This condition should be put in the same class with neuro-paralytic keratitis; it ends in perforation of the cornea, whilst the symptoms of reaction are only slightly marked. Keratomalacia is generally followed by death. Anatomical and pathological reports have made clear the meningo-encephalic nature of this disease, which attacks very young, premature, or weakly children.

Herpes of the Cornea.

Neuralgic herpes of the cornea is accompanied by painful symptoms in the trigeminal region and by hypoæsthesia, or even anæsthesia, of the cornea. We have just seen that certain meningeal conditions produce an analogous syndrome. The corneal lesions of neuro-paralytic influenzal keratitis, with polycyclic contours, for example, are absolutely identical with those of corneal herpes. On the other hand, the corneal anæsthesia of herpes zoster is also accompanied by vesicular eruption, the ulceration of which assumes a polycyclic form. It would be of interest to examine the cerebro-spinal fluid of patients suffering from neuralgic herpes of the cornea. This disease is doubtless connected with a slight affection of the Gasserian ganglion, allied to a defective condition of the meninges.

Ophthalmic Herpes.

In herpes zoster corneal anæsthesia is to be expected. The vesicular eruption rapidly assumes a polycyclic shape. Furthermore, herpes zoster is characterised by painful phenomena, to which we shall return later.

Basing their data on a series of 21 cases of thoracic herpes zoster, with autopsy, Head and Campbell have shown that the condition is one of inflammatory and hæmorrhagic lesions situate at the levels of the spinal ganglia. This theory, reserved at first for spinal herpes zoster, must be extended to cover facial herpes. André Thomas and Henyer found the same type of inflammatory and hæmorrhagic lesions at the level of the Gasserian ganglion.[3]

---

[1] Société de Neurologie, June, 1920.

[2] Monbrun, A.: Archives d'ophtalmologie, August, 1919.

Herpes zoster is very often accompanied by cerebrospinal fluid reactions—lymphocytosis and albuminosis. We have always noticed this fact in the numerous cases we have studied under Professor de Lapersonne. Certain types of herpes zoster are perhaps due to an undetermined infection, "epidemic, non-relapsing, and contagious," as claimed by Landouzy. But very different diseases may induce herpes zoster—syphilis, tuberculosis, pneumonia, eruptive fevers, influenza, typhoid, diphtheria. MM. Achard and Laubry, Pautrier and Clement Simon, have seen it following spinal anæsthesia. It is known that the arachnoid and the pia mater are inserted in the dural cavity of the Gasserian ganglion, and that the latter is directly connected with the cerebro-spinal fluid. Herpes zoster is induced by a meningo-Gasserian lesion. And it is the affection of the Gasserian ganglion which produces corneal anæsthesia and the symptoms common to herpes zoster, to neuro-paralytic keratitis, and to certain forms of corneal herpes.

Painful Anæsthesia of the Trigeminus.

Herpes zoster, neuralgic herpes, and certain forms of neuro-paralytic keratitis are accompanied by neuralgia in the trigeminal region; these painful phenomena are to be contrasted with anæsthesia of the tegument. It is interesting to study this dissociation of the objective and subjective sensibility of the trigeminus. Moreover, the trigeminus contains sympathetic fibres of the cerebro-spinal system. Some of these sympathetic fibres lead directly to the branches of the trigeminus, others to the Gasserian ganglion (sympathetic Gasserian nerve fibres of François Franck).

In 1916 one of the writers investigated pains of the trigeminal tract of causalgic type due to "alteration of the sympathetic in certain wounds of the eye and orbit."[4] One of our wounded cases presented at the same time a complete anæsthesia of the whole trigeminal tract. Herpes zoster completely effects this painful anæsthesia. We know that Déjerine and Thomas, and Head and Campbell, attribute a certain importance to the sympathetic in intercostal herpes zoster. In 1919 Sicard, Roger, and Vernet insisted upon the rôle of the sympathetic and upon the causalgic character of the pains of herpes zoster. We consider that in herpes zoster, neuralgic herpes, and certain forms of neuroparalytic keratitis a Gasserian lesion attacks at the same time the true nerve-fibres of the trigeminus, producing anæsthesia of the tegument, and its sympathetic nerve-fibres, causing pain.

This theory is important from the point of view of surgery of the Gasserian ganglion. Resection of the ganglion and retro-Gasserian radicotomy anæsthetise the tegument innervated by the trigeminus, too often producing neuro-paralytic keratitis, but they do not always cure facial neuralgia, since the attachment of the sympathetic to the trigeminus is partly at the level of the ganglion and partly below it.

LACK OF LAUNDRIES IN PARIS.

(FROM A FREQUENT PARIS CORRESPONDENT.)

THE annual fête day of the Paris washerwomen has gone by—it used to coincide with the Mid-Lent Carnival—when the Queen of Beauty is elected to preside over the rejoicings, being chosen among the laundresses. But modern industrialism, steam-laundries, the high price of coal, and the general circumstances of life prevalent in Paris have played havoc with an ancient and picturesque custom. There was a time when the Seine sufficed for the washing of Paris linen, and nothing can be better or more natural than to wash clothes in running water and hang them out to dry in the open air and sunshine, so long as such treatment of the river does not affect its value for the community in other ways. There are little recesses on the banks of the Seine where for centuries the laundress of Paris earned her living free from rent. During the reign of Louis XV. a man named Marie obtained permission to instal a houseboat near the Pont Louis XV., so constructed as to serve for a laundry. Here, in a sheltered partition, each laundress could wash her goods in the running water, and it was her habit, when the season allowed, to wear flowers. The presence of so many women, sometimes gaily bedecked with flowers, gave animation to the banks of the Seine; and, as they were washing close together, the Queen of Beauty could be more easily selected among them than if they had been engaged on some other occupation.

The Passing of the Houseboat Laundry.

Time, however, wiped these mediæval pictures off the canvas. Paris spread out and the river ceased to be the centre of the city. The houseboat laundries, which had become very numerous, decreased in numbers, and by 1849 only 80 remained, and a Parliamentary Committee was appointed to inquire into them and the whole laundry situation of the city. The reporter for the committee, Mr. Armand, argued that dirty linen was a cause of disease and that the fact of its existence was a symptom of laziness and, if not overcome, of moral decadence. But as a consequence it was decided to build baths and washhouses in districts that were some distance from the Seine, for in all parts of the town there would be linen to wash. The first of these new washhouses was constructed in the old insalubrious quarter of the Temple. It was called the Bain Lavoir Napoléon and was opened in 1853. As these establishments increased in number, the houseboat laundries, such as were left, disappeared one by one; their picturesque features had largely gone before. When the danger had thus ceased to exist a scare was started that the Seine was contaminated by the dirty linen, but by that time the sewers, or the overflow from the sewers, were in operation as real dangers. It was decided that no new floating laundries should be allowed, and to-day there only remain three or four which are in the last stage of decrepitude and cannot float much longer. The days of the laundry-boat are numbered and a popular feature of Paris life is fading away. What is more serious far is the fact that the other laundries are also disappearing, the picturesqueness which supported the boats being absent from the washhouses.

A Substitute Must be Found.

Yet Paris must wash its dirty linen. Before the war there were 350 public washhouses; but the space they occupied is now wanted for new offices, warehouses, banks, and even kinemas. Already 184 washhouses have been abolished. It must be borne in mind that in the tenement-houses and flats of Paris there are no conveniences for washing, no boiler, no little back garden or yard where the linen can be hung to dry. The housewife takes her linen to the public washhouse and pays a small sum for the necessary accommodation to wash it. The majority of families have not the means to give their linen to laundries; they must wash at least a considerable part of it themselves. The large steam-laundries that take in the linen of families and hotels are established in the outskirts of Paris, notably at Boulogne, where they have the necessary room, and with a motor-car carry the linen to and from town, manage very well. But the charges made are ruinous to all but the wealthy. If the poor and persons of moderate means cannot get their linen washed on reasonable terms, public health must suffer. But if the Mid-Lent Carnival has this year so far forgotten its traditions as to select for its Queen of Beauty a typist instead of a washerwoman, that is no reason why public attention should not be called to this public grievance. Some remedy may then be found, and the festival will have served a good purpose.

THE LANCET.

LONDON: SATURDAY, APRIL 2, 1921.

The Action of X Rays on Living Tissues.

IN some respects it may be said that the general physiological effects of X rays have not received the experimental study that they merit. It is only natural that in the treatment of disease by these rays attention has been focussed upon the affected structures, the careful observation of which, combined with experimental investigation, has resulted in a very large number of facts being ascertained. The microscopic findings, indeed, form a separate branch of pathology which may conveniently be included in the term radio-pathology. Such detailed studies have provided a basis for a rational interpretation of the various processes by which a malignant tumour, when irradiated in vivo, may be arrested in its growth, diminish in size, and possibly disappear in the course of time. It is, however, unlikely that this sequence of changes occurs simply as a result of the irradiation which the tumour cells have undergone, for the normal tissues of the host also share to some extent in the exposure to the rays. The nature of this physiological reaction will largely depend on the conditions under which the irradiation is carried out. In our present issue an account of some experimental studies is given by Dr. IVAN I. MANOUKHIN. The author has come to the conclusion that as a result of exposing the spleen to X rays leucocytolysins are set free in the blood. The action of such bodies, as their name indicates, is to effect a solution of the leucocytes, a process which the author looks upon as a necessary step in the successful combat of certain diseases in the body. The experimental basis of this work was provided by monkeys and guinea-pigs, and Dr. MANOUKHIN satisfied himself that subsequent to an exposure of the spleen to X rays the blood shows an increased content of bacteriolysins, agglutinins, and other antibodies.

Starting from this basis Dr. MANOUKHIN carried out a large amount of therapeutic work in cases of tuberculosis, tetanus, typhoid, and other diseases, the main feature of such treatment being the irradiation of the spleens of the patients. An important supplement to this treatment is mentioned by the author; 10 minutes after the X rays are given blood is obtained from the patients, and the serum from this is readministered to them in the form of gelatin capsules. The line of investigation seems one of considerable importance, and will probably stimulate further inquiry into the physiological processes which occur among the various organs of the body after irradiation. Since 1903, when SENN drew attention to the direct effect of X rays upon the spleen in cases of leukæmia, a great deal of work has been done upon the blood changes which occur in animals after exposure to X rays. The researches of AUBERTIN and BEAUJARD in 1908 upon guinea-pigs stand out as one of the most important of the early contributions to the subject; they came to the conclusion that not only are the circulatory elements of the blood affected by the rays, but that some disturbance is produced in the bone-marrow. They found that a medium dose of X rays caused a condition of hyper-activity of the bone-marrow which was the more accentuated the more marked the decrease in the leucocyte content of the blood.

Recent observations by Dr. J. C. MOTTRAM have shown that individuals who have been exposed to repeated small doses of the penetrating gamma rays suffer a serious diminution not only in their circulating leucocytes but also in their red cells. In extreme cases he showed that this may result in an aplastic pernicious anæmia. Last week we reported the untimely and tragic death of Dr. IRONSIDE BRUCE, who has fallen a victim to a blood disease of the above kind. It can only be surmised that, during the course of his radiological work, in alleviating the suffering of others Dr. BRUCE received fractional doses of radiation, the effects of which manifested themselves with startling suddenness; for he died after only a brief illness. Such an event may cause apprehension among radiologists generally. The dangers attending the use of X rays are only now being fully revealed, and it is recognised that these fall into two categories: the superficial damage to the skin caused by the softer types of X rays resulting in dermatitis or still graver conditions; and the damage to the deeper structures, including the blood-forming organs, caused by the more penetrating types of X rays and the gamma rays from radio-active substances. It must be admitted that the conditions under which a great deal of the radiological work of the country is done at present are of an exacting nature. The main factors detrimental to the health of operators appear to be (1) fractional doses of the rays they are using, owing to insufficient protection; (2) the fouling of the atmosphere due to high tension discharges and bad ventilation; and (3) the necessity for a number of hours per day being spent in the dark room. The difficulties of providing adequate safeguards to health under the varied conditions of radiographic and radiotherapeutic work are considerable, but certainly not insurmountable, and we look with confidence to radiologists to overcome these difficulties, so that the practice of radiology may continue under a regime in which the personal safety of the operator has been made the subject of scientific investigation. To initiate such a regime was, we understand, Dr. BRUCE'S earnest wish, and its inauguration would be the most fitting memorial to his life-work.

◆

Hospital Administration: A Test Case.

IT should be a great help to the quiet solution of the problems of hospital administration throughout the country to have them worked out on the stage in the lime-light and with a full orchestra. For this reason we may all be thankful to Bradford. There everything has conspired to produce a dramatic effect; last of all the Boundary Extension Inquiry, which has given a fine opportunity to representative health officers of other sanitary districts to say what they think of municipal health administration as judged by its results in the county borough of Bradford. The city, said one, was badly scavenged and had a persistently high infant mortality rate; the chances of prospective mothers dying in childbirth, said another, were twice as great at Bradford as anywhere else in the West Riding, largely owing to filthy homes. We quote the harsh statements apart from their context, as has been done widely in the daily press, but without endorsing their conclusions. Cause and effect are not always easy to trace in health matters, and we have a questionable precedent supplied by the Minister of Health himself last week, when attributing the fall in infant mortality in London to the maternity benefit under the Insurance Acts. Efficient scavenging and unanxious motherhood are both good things, even though they must compete with many others for an immediate effect on vital statistics. But admitting all this, it is equally certain that the public health service in Bradford with its 27 rate-paid doctors has not yet demonstrated by its results the necessity for doing away with the voluntary hospital system, and that, without mincing words, is what the proposals of Dr. J. J. BUCHAN, medical officer of health for Bradford, amount to.

The local medical advisory council does not share Dr. BUCHAN'S views, but this excellent institution, which consists of three consultants, nine general practitioners, and two whole-time officers, did not come into being till last December, and has only just presented its report, a unanimous one, on the proposed municipal hospital of St. Luke's. The proposal is, it may be remembered, to provide a total of 1148 hospital beds, which, judging by the actual experience of running expenses at the Royal Infirmary and the tuberculosis sanatorium of the Insurance Committee, would entail a cost of at least 16s. per annum per head of the population of Bradford. Not that this would be a high price to pay for a complete system of municipal health, but the advisory council contends with justice that such a levy at the present time would cut off at its source most of the revenue of the voluntary hospitals. A deficiency of in-patient beds is frankly admitted by the advisory council, which therefore approves the St. Luke's scheme in so far as it is necessary to supplement the present provision of hospital beds and to make this provision adequate. But on Sir NAPIER BURNETT'S estimate of three beds per 1000 of population, Bradford would require no more than 900 hospital beds in all, or only 600 of the additional 1148 suggested. The casualty departments of the voluntary hospitals already meet local needs, their out-patient departments suffice for the reduced demand brought about by domiciliary treatment under the Insurance Acts, and facilities for treatment of eye, ear, nose, and throat might be provided by coöperation with the existing special hospitals. The alternative scheme set forth by the advisory council appears on the face of it to be a thoroughly business-like one. It proposes the establishment of a joint hospital board with executive powers enabling it to coördinate all the hospitals in the city, to allocate special work, to avoid overlapping, to give first-hand information on hospital matters to the municipal health committee, to appoint the visiting staffs, to select and nominate applicants to all vacant posts. At St. Luke's itself it advocates a practitioners' ward into which patients might be sent for treatment by their own medical attendants; apart from this, the appointment of the staff to be made on the lines recently adopted at the Paddington Infirmary, London, under the St. Mary's Hospital scheme. Such a staff would be made up of four physicians, four surgeons, one obstetrician, one ophthalmic surgeon, one aural surgeon, one pathologist, one radiologist, and two anæsthetists, and, in addition, beds should be placed at the disposal of the tuberculosis officer.

We believe that the scheme substantially as suggested, if it could be carried out with the full and hearty concurrence of all those concerned, would indeed meet the needs of Bradford and provide a nucleus for future development, whether along municipal or voluntary lines. It contains the essentials of continuity with the past without unduly pledging the future. It has a proper regard for economy both in money, materials, and personnel. Whether all parties in Bradford are prepared to sink their grievances, some of them very real ones, for the common good remains to be seen. The eyes of the public health workers of the country are fixed upon them; this is a critical position, and no one will mistake for weakness the conciliatory attitude of true statesmanship.

◆

Intussusception.

INTUSSUSCEPTION in its acute form among children is a disease which even at the present time is exceedingly fatal, but this high mortality is not inevitable and is due very largely to delay in diagnosis. Mr. C. P. B. CLUBBE, of Sydney, N.S.W., a second edition of whose useful book [1] has recently appeared, has had a relatively large experience of the condition, yet it is, fortunately, not of very frequent occurrence, and this, no doubt, partly accounts for the fact that when it does occur it is not more readily diagnosed. Nevertheless, it is not difficult to recognise. A previously healthy child is seized quite suddenly, screams, turns pale, vomits, and in a short time seems to recover itself, only to cry again at intervals as if in pain. These symptoms are not in themselves diagnostic, but they become so when coupled with the fact that in 97 per cent. of cases blood is passed by the bowel *in from 2 to 10 hours*. Treatment carried out at this stage will probably result in the patient's recovery, yet in very many cases the diagnosis is not made for two or three days, by which time the child is exhausted and collapsed and is unlikely to survive an operation for more than a few hours. It must be admitted that this common delay in diagnosis may be due in part to inefficient teaching. The description of the disease is in some text-books actually misleading; the early passage of blood per rectum is insufficiently emphasised, and the impression is conveyed that the acuteness of the disease, and therefore the urgency of operation, is to be gauged by the degree of collapse seen in the patient. Yet in every case, except in the very rare condition of chronic intussusception usually found in adults, the disease is essentially acute from the very start, and by the time collapse is seen the patient is almost beyond the help of surgery. The treatment of intussusception by injection into the bowel from below has now been abandoned in favour of operative treatment. Mr. CLUBBE, however, while advocating operation in every case, believes that a partial reduction of the intussusception may be obtained by a preliminary injection and that the duration of the operation may be in this way shortened. His conclusions in most other respects do not differ materially from the accepted views, but for the reasons already indicated his book should be widely read by those whose duty it is to ensure that every case of intussusception is diagnosed and treated at an early stage of the disease.

Annotations.

"Ne quid nimis."

IMMUNITY AND TUBERCULOSIS.

WE can count from memory at least three new antiserums and four new tuberculosis vaccines which have come to our notice since the war ended—most of them with the blast of trumpets in the daily press—and a reference to contemporary medical journals would reveal a considerable addition to the number. There is also a chapter of immunology just opening, with accounts of the protective powers of certain special types of protoplasm against the tubercle bacillus. Witness the almost supernatural accounts of recent experiments with the caterpillar and the snail in destroying the inoculated tubercle bacillus. These accounts recall the early records of Richet's experiments on the sea anemone and anaphylaxis when immunologists paused in wonderment. And the results may not be dissimilar—fascinating and yet disappointing in their application to man. It is essential, therefore, that if we strive for the mastery over the tubercle bacillus we strive by right methods. The late Sir Michael Foster once said that the physiologist should exercise his imagination to the full outside the laboratory, and should forthwith eschew it when he reached his bench. This warning is probably more needed now than at any time since Darwin first preached evolution. It has also been said that when the bacteriologist suffers from nightmare he is haunted in his dreams by a hideous row of control experiments which he has neglected to perform. We could almost find it in our hearts to wish that some men suffered from this nightmare a little oftener. Failure to control experiments is a serious mental aberration on the part of the bacteriologist, and when the clinician turns bacteriologist he is particularly liable to this form of mental disorder. How many valueless tests have been made in the study of tuberculosis, and how many wrong conclusions drawn by failure to make controls with the normal? We need to control the virulence and purity of our cultures, the toxicity of our media, and a hundred other factors; and when we come to use antiserums there is a whole new field of control research awaiting us on the influence of normal serum on immune bodies and on pyrexia and metabolic processes generally, which at present we have barely visualised. Nor are these the only factors. The physician, if he be honest with himself in testing a tuberculosis vaccine or antiserum, must make controls as to dosage and auto-inoculation; he must compare the normal individual with the abnormal. In the ideal experiment there is only one variable factor, the one on which we are at the moment researching; all else is stabilised. These are conditions we should aim at. Here especially is the clinician's pitfall, because it is hard to equalise things by the bedside. And the climax of research is reached in those statistical results known as "cures" which beset the path of every worker. No phase of work is more readily misinterpreted. A little difference in the method of choosing cases, a little carelessness in following up our results, a little variation in the "end-point" of a clinical reaction which is rarely as clearly defined as a titration in volumetric analysis, a little undue optimism about that fatal phrase "quiescent lesion," and it is all up with our statistics. The penalty is paid by the patients. One moral is to pay a vast deal more respect to the accurate meaning of the word specific. Having exalted the term to a special place in the vocabulary of immunity, let us not prostitute it to the use of every new and untried remedy in vaccine and serum therapy.

THE COMPARATIVE METHOD IN MEDICINE.

FOR many years Sir Clifford Allbutt has been advocating the consolidation of all branches of medical study in the belief that without the comparative method medicine cannot make active growth on the larger lines. Professor F. Hobday's lecture, which we print elsewhere, delivered at a combined medical and veterinary meeting, gives examples of the peril to man from animal diseases, grave enough in themselves to drive this lesson home. But there is far more in it than this, as Professor Hobday indicates—namely, that only in the light of disease as a whole can its parts be adequately known and its intimate laws understood. The comparative method has been fertile of results in the spheres of anatomy and morphology, as, indeed, it has been the groundwork of modern developments in the study of history, language, and religion. Much good might come from affiliating a section of veterinary medicine with the Royal Society of Medicine, or, perhaps better, from organising a section of comparative medicine at which graduates of both professions could discuss subjects of mutual interest. The large attendance at the discussion on March 14th to discuss the Eradication of Tuberculosis in Man and Animals confirms the interest taken in these borderland topics. Cambridge University has its field laboratories and its agricultural department, and, apart from any other motive, it would probably pay pedigree stock-breeders and nurserymen very well to endow an institute for practical and theoretical work on comparative medicine, both of plants and animals. An endless variety of experience and opportunities for research would be afforded by comparative pathology.

THE UROHÆMOLYTIC COEFFICIENT.

Professor Alfredo Amati, of the University of Naples,[1] has been conducting some new researches on urinary hæmolysis as an aid to the diagnosis of nephritis and malignant disease. In his first series of experiments his object was to investigate in what way the red cells behaved when immersed in the urine of healthy persons, and what influence the specific gravity, reaction, amount of chlorides, urea, and molecular concentration had upon the phenomenon of hæmolysis. The result of this first series was to show that normal urine is never hæmolytic, but, on the contrary, has in the majority of cases an antihæmolytic action on the blood cells. And an interesting point is that this antihæmolytic action bears no direct relation to the specific gravity, reaction, quantity of urea and chlorides, or cryoscopic delta. Apart from urea, which it is known has no action on the red cells, it was found that urines with low specific gravity, deficiency of chlorides, and high cryoscopic delta did not cause hæmolysis, almost as if they did not obey the physical laws of osmosis, thus confirming the hypothesis that in the urine of healthy persons there is an antihæmolytic substance which renders it resistant to these physical laws. The second series of experiments were with pathological hæmolytic urines, of which, after long investigation, Professor Amati only found six—three from cases of chronic interstitial nephritis, one in chronic parenchymatous nephritis, one with carcinoma of the uterus, and the last with sarcoma of the sternum. The specific gravity, amount of salts, &c., seemed to have very slight influence on the phenomenon of hæmolysis in these cases, but the reaction was not constant. The inconclusive nature of these experiments led Professor Amati to a third series in which he investigated the effect of adding distilled water to urine—i.e., if the urine of a healthy person is not hæmolytic how much distilled water must be added to make it globulicidal. He took a series of eight test-tubes, the first containing 6 c.cm. urine alone, the next 5½ c.cm. urine and ½ c.cm. distilled water, and so on, the eighth having ½ c.cm. urine and 5½ c.cm. distilled water. The patient's finger is pricked and two drops of blood allowed to fall into each test-tube, which are then placed in an incubator at 37° C. for 2-24 hours. The results found were that physiological urines in order to become hæmolytic had to have a marked dilution with distilled water, usually 5 water to 1 urine. The important point is that the degree of dilution is constant in all urines, and if the smallest dilution required to render a urine hæmolytic be called the urohæmolytic coefficient, it may be said that this coefficient is constant in normal urine, being usually equal to $\frac{5}{8}$, but may oscillate between $\frac{3}{8}$ and $\frac{10}{11}$. With pathological urines, however, using the same dilution, it was found that in nephritics and patients with malignant disease this urohæmolytic coefficient becomes considerably changed or even inverted, ranging between $\frac{1}{11}$, $\frac{1}{6}$, and $\frac{1}{3}$. We call the attention of observers to these researches which promise to be useful for diagnostic purposes; the method is simple and easy, and within the range of everyone, and if Professor Amati's conclusions are verified the investigation of the urohæmolytic coefficient may become one of the common laboratory methods and of utility in doubtful cases of nephritis and malignant disease.

---

[1] Il Policlinico, Practical Section, Feb. 28th, 1921.

A FRENCH REVIEW OF MEDICAL PROGRESS.

THE *Archives de Médecine et de Pharmacie Militaires*, published by order of the Minister of War, proposes to issue every three months a "medical chronicle" drawing attention to the notable facts and ideas which have during the period marked the progress of medicine. The present chronicle is from the pen of Dr. de Lavergne, professor at the Military Medical School of Val-de-Grâce, and recounts striking advances in medicine which have come to notice during the war. Spirochætosis ictero-hæmorrhagica was previously unknown, also the broncho-spirochætosis of Castellani, apparently brought to France by Arab troops from Africa; Noguchi has proved yellow fever to be due to another spirochæte. Gas poisoning was a new disease, and amœbic dysentery was almost unheard of in France, where only 13 cases of endemic origin had been reported up to July, 1914. Paratyphoid-A fever was very rare, too, until imported, probably by troops from Algeria and Morocco. Then encephalitis lethargica, a polymorphic disease, was discriminated about 1918. Its virus is a filter-passer which sets up the disease in injected monkeys and rabbits. It is a question whether various of the rarer but well differentiated nervous diseases which we so little understand may not be sporadic cases of this infectious disease. The nature of chorea is in consequence being rediscussed; some bold spirits even ask whether hysteria in certain of its manifestations may not be the expression of an infectious disease. We shall probably in future inject serums protective against both gas gangrene and tetanus, and surgeons have found in the war that the bacteriologists can help them, as for years the physicians have known. The cause of influenza is not completely understood. It appears to be a filter-passer which causes an illness, in itself slight, but opening the way for serious secondary infections against which a patient may be protected by suitable vaccines. The cause of mumps is also a filter-passer, and, inoculated within the parotid of the cat, after nine days' incubation it excites a parotitis, which is sometimes complicated by orchitis. The cause of another infectious disease, typhus, is not yet known, though the disease reproduces itself (Ch. Nicolle) in the guinea-pig injected with the blood of a typhus patient, and cultures of *Bacillus proteus* are agglutinated by serum from cases of typhus. Levaditi and A. Marie claim they have proved the existence of two races of *Treponema pallidum*, one of which is neurotropic and attacks the nervous system, while the other, dermotropic, attacks only the skin. Shock is considered due (Delbet) to the absorption of toxins, products of the crushing of muscles. Then there is Widal's "hæmoclasic reaction," due to the entry into the organism of a heterogeneous albumin. This reaction is recognised by examination of the blood, by the blood pressure, or by alteration in the refractive index of the serum. Sometimes no symptoms follow, sometimes we have evidence of anaphylaxis. Examples are asthma from the smell of sheep, giant urticaria after certain foods have been taken, epileptic fits excited by eating chocolate, or an attack of malaria due to the break-up of the rosettes. He and his pupils show it is not only as amino-acids that proteins leave the intestine; they sometimes enter the portal circulation unchanged. One social change due to the war must be mentioned. A man nowadays brought before a discharge board and found to be on medical grounds unfit for service is presumed to be entitled to a disability pension unless the army can show that his unfitness is not due to his service. Antityphoid, anticholera, antitetanic preventive injections formerly debated are now universally accepted. Some prevent typhus by injecting serum of patients convalescing therefrom, and similar proposals are made regarding measles. But, of course, these methods are of themselves insufficient. Places must be kept clean, water must be sterilised when suspicious; a vigilant police at the frontier may keep off plague and typhus—but what do these precautions avail if the general population be not educated in proportion, if its own manners and customs are unclean and unhygienic? It is clear from the zeal with which France is throwing herself into the fight against tuberculosis that her hygienic conscience is thoroughly aroused ...... But Professor de Lavergne's review should be read at length in the original.

OCCUPATIONAL DERMATITIS IN DENTISTS.

DR. C. Guy Lane,[1] assistant dermatologist to the Massachusetts General Hospital, Boston, remarks that occupational dermatitis in dentists has usually been attributed to one of their antiseptics or soaps, and with the exception of Mook, who records a case due to apothesin, no one has associated the skin lesions with the use of local anæsthetics. Dr. Lane has recently had occasion to treat three dentists who presented an irritated condition of the hands, apparently due to their individual susceptibility to procain. This drug was introduced into the United States in 1912, where it appears to be the most widely used local anæsthetic among dentists. In its lesser toxicity, greater solubility and stability it possesses considerable advantages over cocaine. It is neutral in reaction, and its solutions are precipitated by alkaloids and alkaline carbonates, though it is not affected by sodium bicarbonate. The eruption in Dr. Lane's cases consisted of circinate erythematous areas with fissures on both palms and about the fingers, and was attended with intense itching. The lesions in the palms closely resembled those of an epidermophyton infection, but examination of the scales was negative. Skin tests with procain solutions revealed an individual susceptibility in each case, there being intense redness and itching within 24 hours at the points of inoculation. A rapid cure followed the discontinuance of the use of the drug, or in protecting the hands by wearing rubber gloves.

ETHNOLOGY FROM AN EASY CHAIR.

THIS is the alternative title of Lieut.-Colonel T. R. St. Johnston's delightful book on the Islanders of the Pacific.[2] Here and there we do not follow the medical author's arguments, but his title disarms criticism based upon stern logic. Colonel St. Johnston's thesis is that "the Polynesian and the European had in the remote ages of the past one common ancestry, a kinship of common blood." And the following is the author's account of this ancestry. There was once (p. 262) a nation termed "Armenoid," who inhabited the country north of Mesopotamia, and who, several thousand years ago, began one of the well-known tribal migrations. The Armenoids invaded Egypt, got down to the Persian Gulf and invaded India, where to-day the Nagas are probably their descendants. They pushed out the aboriginal inhabitants—i.e., the Dravidians, who were driven down to the Malay Peninsula and the Indonesian islands. Meantime the Armenoids who had gone down to Egypt had worked their way down the Red Sea and eastwards to India where they also came into contact with the Dravidians, and pushed on into the Pacific, intermarrying with the Negrito Pacific aboriginals, and founding the Melanesian peoples of to-day. But the real Polynesians are the descendants of the

---

[1] Archives of Dermatology and Syphilology, March, 1921.

[2] London: T. Fisher Unwin. 1921. Pp. 307. 25s.

Armenoids who came into India by land, and who in their turn were slowly pushed on by the Aryans until they reached Java and the gates of the Pacific not later than the fifth century B.C. They left Java about the beginning of the Christian era, and when they got to the Pacific islands they found there the black, flat-nosed people of whom so many traditions are found in Polynesian legend. Of the connexion between these people and the people in other parts of the world who mined for gold, worshipped the sun, and built great stone temples, we have not space to talk. But we must refer to one passage of Colonel St. Johnston's book, on the Fire Walk ceremony (p. 173) which, as he says, is or was carried out in other parts of the world, Indonesia, Japan, Egypt, and Bulgaria. In the Pacific it is confined to the Polynesian districts, for though found in Fiji it is only in the definitely Polynesian island of Benga that it exists, and is even there confined to one special group of people. Now Virgil gives an account in the Eleventh Book of the Æneid of a Fire Walk ceremony held at Soracte in honour of Apollo, similar in every way to the Polynesian ceremony described by Colonel St. Johnston. Here are his words:—

> "Summe deum, sancti custos Soractis Apollo,
> Quem primi colimus, cui pineus ardor acervo
> Pascitur, et medium freti pietate per ignem
> Cultores multa premimus vestigia pruna."

Highest of gods, Apollo, guardian of holy Soracte, thou whose chief worshippers we are, thou for whom the pile of burning pine wood is fed, while we upborne by faith press our footsteps in the glowing embers. ...... Pliny (Hist. Nat., VII., 2), commenting on this custom, says that the power to walk through the blazing wood embers was confined to one family, the Hirpi, and Servius, the commentator, quotes Varro as saying that they rubbed their feet with a drug, "medicamento plantas tingunt." So we find an identical ceremony in primitive Italy and in Polynesia. Dr. Warde Fowler, in his Roman Essays and Interpretations, has drawn a most interesting picture of the extraordinary parallelism between certain customs, especially of divination, which exists between those of primitive Italy and certain tribes of modern Borneo, such as the Kayans and Kenyahs. The Kayans are partly of Caucasian blood, and are believed to have found their way into Borneo from Central Asia by way of Burma; Borneo, it is true, is not Polynesia, but it is a stepping-stone thither from India. So here we have another link between ancient Italy and the Far East, and the sum of Colonel St. Johnston's speculations is that the Polynesian race must not be allowed to die out. One point more, and that a very speculative one. There is a tradition that about the twelfth century a ship with whites on board arrived at Oahu, and that this is probably the same ship in which Paumaha, of Oahu, brought back two white gods or priests to Hawaii. Could these white men have been Nestorian missionaries? In the sixth century there was a flourishing Nestorian church in Malabar, and in the eighth century a Nestorian patriarch of China. It is not impossible, therefore, that by the twelfth century some enterprising missionaries may have got into Polynesia, though there is no record left of the pilgrimage.

THE FOURTH VENEREAL DISEASE.

ACCORDING to Dr. William M. Donovan,[1] Instructor in clinical medicine at the University of Wisconsin Medical School, who records an illustrative case, the subject of the so-called "fourth venereal disease," or specific ulcerative and gangrenous balano-postbitis has received comparatively little attention. The condition is an acute inflammatory disease of the glans penis and opposed surface of the prepuce, characterised clinically by ulceration and at times gangrene, with a copious flow of fœtid pus, and caused by the symbiosis of a spirochæte and fusiform bacillus morphologically indistinguishable from those met with in Vincent's angina. Predisposing causes are (1) a redundant prepuce with tendency to phimosis, and (2) an unclean preputial sac with its decomposing smegma. The comparative frequency of the condition is shown by the fact that it constitutes 2–3 per cent. of the cases seen at the Hôpital du Midi. The period of incubation ranges from two to eight days. Subjectively there is a mild itching followed by constant burning pain in the preputial sac and extreme tenderness of the penis on manipulation. Exfoliation of the epithelium of the sulcus, prepuce, and glans takes place and is followed by ulceration. Œdema of the whole penis, phimosis with heat and redness, and palpable dorsal lymph vessels are common. Bilateral inguinal adenitis is frequent, but suppuration does not occur. Constitutional symptoms are absent except in severe cases which are attended by prostration, fever, vomiting, &c. In cases with much phimosis gangrene is liable to supervene unless proper treatment is instituted, but when there is no such phimosis the condition may subside spontaneously with the ordinary methods of cleanliness in two or three weeks. The disease is sometimes complicated by the coexistence of syphilis. The diagnosis is established by the presence of the spirochæte and fusiform bacillus in the pus. Prophylaxis consists in the performance of circumcision. Cauterisation is contra-indicated, as it renders anaerobic conditions possible beneath the coagulated albumin. The following treatment is recommended by Dr. Donovan: A dorsal slit should be made in the phimosis so as to enable remedies to be applied and favour aerobic conditions; the sac should be irrigated every few hours with peroxide of hydrogen solution, and powdered salvarsan or neo-salvarsan should be applied daily to the ulcers.

ANILINE AND CANCER OF THE BLADDER.

THE International Labour Office of the League of Nations at Geneva has established a special section, under the direction of Dr. Carozzi, to deal with industrial hygiene. This section has now produced its first publication, a booklet[1] dealing with cancer of the bladder among workers manipulating aniline. Rather inconclusive reports have been issued on this subject in recent years, and we welcome this reasoned summary of all available evidence, feeling that anything which may throw light upon conditions or influences leading up to malignancy cannot fail in the long run to prove of value to the whole cancer problem. While at the present time the development of the dye industry in this country gives special interest to the subject. The earlier cases of cancer of the bladder were reported from Frankfort-on-Main, but statistics now published include other cases studied by Leuenberger at Basle, which is another centre of the dye industry. The figures indicate that among 15,800 patients treated at the surgical clinic of this town from 1861–1900, only 6 (0·04 per cent.) were tumours of the bladder; while from 1901–10, after the chemical industry was established, among 9650 cases 16 (0·2 per cent.) were tumours of the bladder and 12 of these cases occurred among workers in the dye industry. The occurrence of these cases at Basle establishes a definite relation between the industry and tumours of the bladder. The condition itself takes varying periods to develop, depending upon the chemical influence concerned; less than three years' exposure is claimed to be sufficient in the case of benzidine, five years in the case of naphthylamine, and 12 for rubine and fuchsine. The first symptom is frequently hæmaturia with dysuria, and stranguria; but bladder irritation, disappearing and reappearing, may precede by a considerable time more serious alterations. Lack of personal hygiene, malnutrition, and alcoholism favour the condition, and workers who take great care of their skin show a smaller number of cases. Papillary tumours, adenomata, and adenocarcinomata occur; but the majority of the tumours have an extraordinary polymorphism. These tumours result from "an atypical growth of the epithelium of the mucous membrane, with the formation of microscopic and macroscopic papilloma, the development of granulated tumours, carcinoma, adenocarcinoma, sarcoma, &c." Doubt seems to be present in the first stages of any case as to whether it is benign or malignant. For some indefinite reason a sharp distinction is drawn in the report between tumours of the bladder due to aniline compounds, and epithelial carcinomata as seen among workers manipulating tar, shale oils, and pitch. In each case at first there is an overgrowth of epithelial tissue, papilloma of the bladder in the one case and skin warts in the other. In each case difficulty arises in determining when the overgrowth has taken on malignant characters; O'Donovan[2] holds that in dealing with tar cancer we have in all probability a carcinomatous histological picture from the beginning. In each case metastasis is not the rule. In each case there is a chemical similarity in the bodies bringing about the tissue changes; aniline is a benzene compound, while tar, paraffin, and pitch are all distillation products of vegetable matter containing benzene derivatives. Determination, in these instances of occupational cancers, of the precise substances which can induce hyperplasia in living tissues might go far to disclosing the first stage from normality to abnormality upon which malignancy is finally superimposed. Probably chimney-sweeps' cancer, induced by coal-tar products in soot, and cancer of the lip and buccal cavity, induced by products of tobacco distillation, would be found to have a similar primary cause.

[1] American Journal of the Medical Sciences, February, 1921.

[1] Cancer of the Bladder among Workers in Aniline Factories. Studies and Reports, Series F, No. 1. International Labour Office, Geneva. February, 1921.

Considerable effort has been made to discover which chemical products are at fault. Evidence points to the aminobenzenes, particularly benzidene and β-naphthylamine. The path of entry into the body is not clear; probably the respiratory and digestive tracts, as well as the skin, each play their part; but the analogy of T.N.T. poisoning would suggest that the skin is the most important. The path of exit is indicated by the pathological results; Kuchenberger claims to have found a colour test by which the presence in the urine of amino-aromatic compounds can be demonstrated. The value of this test, like Webster's test among T.N.T. workers, is to establish the presence of exposure to risk, and the necessity for more efficient means of prophylaxis. Exposure can be minimised by good ventilation, rigorous cleanliness, dust prevention or removal, short periods of work, clean overalls, and a clean skin. Periodical medical examination, including cystoscopy, is needed. Milk should be given to the workers, and alcohol and smoking prohibited.

This pamphlet, which contains a valuable bibliography of the subject dealt with, will, we hope, only be the forerunner of other interesting studies concerned with diseases peculiar to industry.

ACCOMMODATION FOR SEAMEN.

WE are informed that the town council of Newport (Mon.) has formally complained against the unsatisfactory Regulations of the Board of Trade which permit the present degrading type of accommodation for seamen to continue in the British Merchant Service. The report adopted by the council states that the time is ripe for the revision of the British regulations for the hygiene of crew spaces in order to secure larger cubic space for sailors, and urges that a strong committee representing the Board of Trade, the Ministry of Health, shipowners, shipbuilders, the officers and men of the Merchant Service, port sanitary authorities, and the Admiralty be set up with this object. The council points out that the present British official standards are too low, and in some respects inferior to those insisted upon by many foreign countries and British colonies. The council proceeds to say that the excessive rates for sickness and deaths amongst seamen are closely related to the unfavourable conditions of their lives at sea. The figures per thousand for the Navy and the Merchant Marine, drawn from the best statistics available before the war, strengthen these arguments, though it must be remembered, as we pointed out recently in another connexion, these may be gathered on systems which are not really comparable:—

	Royal Navy, 1913.	Merchant Marine, 1913–14.
Total number of men	126,830	245,619
Death-rate from injury	1·18	5·01
" " disease	2·06	4·1
Total death-rate	3·24	9·11

The Merchant Service would appear to have a death rate from disease which is double, and from injury quadruple, that of the Royal Navy in peace-time. We should have to go back 20 years to find so high a death-rate from disease alone in the Navy, but it is three times higher in the Merchant Service. The report points out that, "apart from the question of providing healthier and brighter housing conditions for the Mercantile Marine in return for their noble self-sacrifice during the war and their heroic work in saving the Allies from starvation and ruin," our foreign competitors are giving their men better accommodation, and British sailors and firemen have shown preference for service in American merchant vessels, where conditions of life are so much better.[1] According to the town council of Newport large numbers of ships have been recently built with the war-time improvements omitted, and this without official interference. A 48-hour week for seamen may possibly in the near future be adopted. In that case crews must be much larger, more accommodation will be quickly required, and it is the more important that we should have good plans ready now. The need for international agreement in this matter is real, for ships pass from country to country and crews are of many nationalities, and the Newport report is sound in urging that the League of Nations should establish a minimum international standard of marine hygiene for sailors' accommodation. The report is to be sent to the Prime Minister, the Board of Trade, the Ministry of Health, and others interested in, and with power over, port sanitary work, from whom we trust it will get the careful attention it deserves. It marks an epoch in the fight for good accommodation for seamen in their ships, where the medical officer of health for Newport, Dr. J. Howard-Jones, has long been a protagonist.

SIR WILLIAM THORBURN.

AT the end of last year, as our Manchester correspondent recorded at the time in our news columns, Sir William Thorburn resigned his appointment as senior honorary surgeon to the Manchester Royal Infirmary, doing so, as we were aware, a little before his time expired in order to devote himself more entirely to the private practice of his specialty. The resignation necessarily carried with it the vacation of the chair of clinical surgery in the University of Manchester. The Council and the Senate of the University, in accepting the double resignation, expressed their appreciation of his services and passed a resolution referring to his distinguished record and skill in the practice of his profession. The very warmth of this expression, which was widely published in the press, has had the embarrassing result of misleading many of Sir William Thorburn's friends to believe that he has retired from practice. We are glad to assure them that this is not the case. He has always remained in full private practice, nor has his connexion with the hospital ceased. At a meeting of the medical board of the Manchester Royal Infirmary, held on March 30th, a resolution was moved and carried confirming the appointment of Sir William Thorburn to continue to give lectures on the surgery of the nervous system and to continue doing surgical work at the Infirmary.

WE regret to record the death, at the age of 55 years, of Dr. Robert Murray Leslie, senior physician to the Prince of Wales Hospital and to the Royal Chest Hospital, City-road.

---

TUBERCULOSIS IN GERMANY.

BY E. G. GLOVER, M.D. GLASG.,
FORMERLY MEDICAL SUPERINTENDENT, BIRMINGHAM MUNICIPAL SANATORIUM, CHELTENHAM.

FROM time to time conflicting newspaper reports reach England as to the exact degree in which Germany has suffered in well-being as the result of the war, and, for this reason, it is perhaps worth while examining the statistical evidence with reference to tuberculosis. The figures given here are taken from the records of the Gesundheitsamt. Tables A and B are concerned merely with the death-rate from tuberculosis, since there is no compulsory notification of infection in Germany, but only a compulsory notification of deaths from tuberculosis.

Annual Death-rate from Tuberculosis of All Organs per 10,000 Living Inhabitants.

A.—Whole of Prussia.			B.—In German towns.			
Year.	Absolute No.	Death-rate.	Year.	No. of districts.	Absolute No. (civil and military).	Death-rate.
1892	—	26·0	1914	386	41,730	16·0
1913	56,861	13·6	1915	383	44,805	16·8
1914	58,577	13·8	1916	383	48,779	18·0
1915	61,606	14·4	1917	383	67,860	25·2
1916	66,544	15·7	1918	373	75,160	28·7
1917	87,032	20·5	1919	365	66,604	27·1
1918	96,844	22·8				

The figures in Table A are for the whole of Prussia, town and country included; in round figures, we may note specially the fall of the death-rate from 26 in 1892 to 13·8 in 1914 and the rise to 22·8 in 1918. As, however, the figures for rural districts always water down the tuberculosis death-rate it is advisable to consider the town death-rate as given in Table B. In this case the figures are for the whole of Germany and deal with the rate in towns of 15,000 inhabitants and over in about 380 districts, the population concerned totalling 25,797,000. The increase from 1914 is again remarkable, and we may say that between 1914 and 1919 100,000 more patients died than might have been expected, calculating from the rates of 1914. These figures are perhaps less illuminating as there is no record for Alsace-Lorraine in 1918–19, and none for Posen in 1919, and over 10,000 other fatal cases have, therefore, not been included.

Owing to the faulty system of notification in Germany, and the frequent lack of differentiation between lung tuberculosis and tuberculosis of all organs, it is difficult to give satisfactory figures with regard to lung disease, but a rough idea may be obtained from Table C, which deals with lung rates in some towns, districts, and and provinces.

TABLE C.—*Death-rate of Lung Tuberculosis per 10,000 Living.*

Place.	1885	1913	1917	1918	1919
Berlin	34·6	16·6	30·4	29·9	23·3
Hessen	29·2	12·5	21·2	20·0	19·0
Bavaria	25·4	14·7	17·0	17·6	—
Prussia	—	12·0	18·2	20·5	—
Munich	—	17·3	21·9	23·9	—
Saxony	25·0	11·4	13·1	Incomplete.	—

The difference between industrial and rural areas in Table C. is very striking. With regard to the increase in the tuberculosis "infection-rate," this can only be guessed in Germany, but going on the assumption that at least twice the total number of deaths represents the number of cases living (and this, in England at any rate, would be a very modest assumption), we may take it that in 1913 there were 200,000 cases, and that in 1918 this figure had risen to 340,000. As a matter of fact, the Gesundheitsamt estimates that there are at present little short of 500,000 cases in Germany, and this is probably true.

A certain amount of corroborative evidence can be had from general health statistics, although naturally less stress can be laid on their probable accuracy. From a report of the Reichs-Versicherung one finds that whereas in 1913 10,400 adults were on the sick-list, in 1919 this number had risen to 43,000; in Hamburg the number of tuberculous patients receiving extra nourishment rose to nearly double in the period from November, 1917, to August, 1919; in Berlin the death-rate for women and children rose from 14 in 1913 to 19 in 1920 (this last figure making due allowance for the influenza epidemic). According to the Berlin Industrial Friendly Society the percentage of deaths caused by tuberculosis, in relation to the total deaths from all causes, is as follows:—

	Men.	Women.
1914	30	32
1917	42	45
1919	35	39

As is well known, a similar rise in tuberculosis death-rates and morbidity-rates occurred in England during the war (speaking from memory, the number of actual deaths in England and Wales rose from 49,000 in 1913 to 58,000 in 1918), but compared with the rates in 1892 it is not nearly so striking as in Germany. The figures before 1892 in Germany are not very reliable or rather not comparable. It is therefore interesting to inquire whether in Germany, as in England, an improvement took place after the conclusion of hostilities. That such an improvement did take place can be gathered from the following figures, which show the half-yearly death-rates per 10,000:—

	First half.	Second half.
1914...	17·5	14·6
1919...	34·4	27·1
1920...	25·6	(?) 16 (incomplete).

All the figures go to show that the highest death-rate was reached in 1918, and that, especially in the second half of 1919, there was a marked improvement which has since continued. The same applies to the statistics for living cases. The figures for the Berlin Krankenkasse show a distinct drop since 1918, and this is confirmed by the Stettin report, but it is interesting to note that in Mannheim (where industrial conditions are very bad) the reverse holds true, especially for infectious patients. Not only has the rate risen there, but whereas in 1918 of all new cases 17 per cent. were infectious, in 1919 21 per cent. were infectious. Whether the rates will shortly fall to the pre-war level is an open question, but taking into account the present food situation in Germany it seems unlikely. As a rough approximation one might say that the present food conditions in Germany are much worse than they were ever in England at the worst time of the war, and that this must affect the next ten years at least, especially amongst those who are at present in youth or adolescence.

Methods of Fighting Tuberculosis.

On the other hand, the fact has to be faced that the present organisation of antituberculosis work in Germany is unable to cope with the problem: firstly, because of lack of money; secondly, because the German is no longer as docile and amenable to health regulations, or, indeed, to any official regulations, as formerly; and thirdly, because the dispensary system has not been effectively organised, especially with regard to treatment and after-treatment. Of course, there are many excellently organised centres, as in Stettin, but in other places these are absent, and in large towns like Berlin there are so many organisations that within a circle of stools the unfortunate patient falls to the ground. The working of the insurance regulations in a town like Berlin is curious. Sick benefit is organised and administered, as in England, through the medium of the Krankenkassen, but tuberculosis work is in the hands of the invalidity department. This is due to the fact that since the invalidity section suffered so much from tuberculosis unemployability they set out, at first, to attempt to cure tuberculous cases; and latterly, to attempt to prevent infection. For this reason the Landes-Versicherung has a well-organised system of dispensaries, sanatoriums, &c.

The uninsured are less fortunate. True, at the Charité (a model University hospital) there exists an organisation where officials of the more needy class, small shopkeepers, shop assistants, and widows and children without means can receive treatment. In *1919*, *6080* were on the books, and in *1920* this rose to 9200. As a side-light on present conditions, it may be noted that in 1919 the figure included 38 authors and artists, a few doctors and lawyers, and several hundred Government officials, many of whom were of high grade. At the Charité the patient pays one-third of his own costs, the employers, if any, are approached to pay another third, and the remainder is found from various sources—e.g., the municipality, the Government, the Deutsche Central-Komitee, or privately.

An additional complication in Berlin was introduced by the extension of the town boundaries. In the suburbs, both rich and poor, regional dispensaries existed for dealing with the diagnosis and home visitation of tuberculosis cases, and these have not yet been absorbed into any central organisation. Both insured and uninsured are dealt with here, and here, as with the Landes-Versicherung and Charité, the families of infected cases are dealt with. It is expected that in the near future this family system will apply to diseases other than tuberculosis. In practice, then, a tuberculous patient is recommended by his private doctor, or by the Kassenarzt (insurance doctor) or by his Poor-law doctor (Armenarzt) to go, or goes of his own initiative, to a local Fürsorgestelle (dispensary), whence, if insured, he is transferred to the Insurance Organisation, or where, if uninsured, various attempts are made to provide him with treatment.

Deficiencies of the System.

But when one comes to inquire what this treatment actually amounts to, the German system, sometimes through no fault of its own, shows up very badly. In all Germany in the year 1918–1919 there were 168 sanatoriums, with 17,500 beds, and for children 172 institutions, with 14,000 beds. This does not include, of course, a number of beds in the various hospitals and Poor-law infirmaries. In Berlin, for example, there are 378 beds in hospitals and 160 in Poor-law infirmaries, mainly for hopeless cases, leaving roughly about 680 available beds in proper tuberculosis sanatoriums. This, for a population of over four million under present conditions of infection, is much too little. It is estimated at the Gesundheitsamt that only 25 per cent. of any new series of cases can get effective sanatorium treatment; the Charité authorities estimate the figure at 35 per cent., and it is at any rate safe to say that 50 per cent. do *not* get adequate treatment. The period of treatment, too, has been reduced, largely through lack of money, to 6–8–10 weeks' duration. Moreover, it is much more difficult for uninsured cases to obtain treatment; the uninsured Fürsorge-Stellen must go from pillar to post begging or purchasing sanatorium accommodation under various organisations in various parts of the province of Brandenburg.

This deficiency in sanatorium treatment would not be serious if at the various dispensaries there was provided effective out-patient treatment or after-treatment. Unfortunately this is not so. The dispensaries are exceedingly well organised as far as diagnosis, statistical records, the supply of printed forms, innumerable recommendation forms, and the dispensing of good advice is concerned; they are also the centre-point for a staff of efficient nurse-supervisors, but the dispensing of medical treatment is practically unknown. There are, indeed, many insurance dispensaries where tuberculin is administered, and the Charité in Berlin has a fairly efficient treatment clinic for uninsured cases, but in general there is no treatment in dispensaries. The patient has the cold comfort of accurate diagnosis, and must thereafter extract what satisfaction he can from printed recommendations. What the dispensaries have done in the past and still try to do is to distribute food, cod-liver oil, and clothing to needy cases, but at the present time this is practically a dead letter. When the tuberculosis patient in Germany asks for bread he is almost literally given a stone, or at least a bread-substitute which closely resembles emery-paper.

In practice, treatment is limited (if one exclude the small amount of sanatorium treatment provided) to home-care, or, as it is euphemistically termed in England, "domiciliary" treatment. This is usually carried out by the Insurance or private doctor. The Poor-law doctor also treats cases, but he is not in great demand; the Brandenburger hates the Poor-law and, indeed, until recently at any rate, treatment by Poor-law officials entailed loss of certain civil rights. The end of the tuberculosis story in Germany is very simple: notification of the patient's death is made under legal statute to the Kreisarzt who is really the police doctor, the house is sterilised, the children are examined, and that is the end.

Some Observations.

Three observations of some interest may be made. Amongst all classes in Germany the relatively alarming increase in tuberculosis is attributed mainly to the effect of the "Hunger-blockade" as it is called, and by the same classes it is held that improvement in tuberculosis is greatly retarded by the transfer to other countries of a large proportion of milk cows. On the other hand, some tuberculosis authorities are, all things considered, very optimistic about the future of the tuberculosis crusade and think that in a comparatively short time after food-supplies approximate to the normal quantity the rates will also fall to normal. The outside observer, remarking as he must, the lean, yellow, under-nourished look of German youths cannot but feel that this bodes ill for the tuberculosis rate in ten or so years' time, and finds such optimism is premature.

The second observation is that England and America have every reason to feel proud of the activities of the various relief missions, especially those of the Quakers, who unobtrusively, but effectively, help in some way to provide children, apprentices, university students (and in the near future, it is hoped, tuberculous cases) with adequate nourishment. It is true that often only the fringe of the problem is touched, still the attempt is one which deserves all praise.

The last observation is that the average German appears to have only a theoretical acquaintance with the principles of fresh-air inhalation; preferably he takes his air well boiled, or at any rate half cooked; real fresh air he relegates to its natural habitat—viz., out of doors. It is worthy of comment that the interior of many tuberculosis institutions is warm enough to make the enthusiastic foreigner mop his inquisitive brow, and to make him sigh for the English system whereby he no sooner enters a tuberculosis centre than he is almost blown out of the exit. In Germany, however, this does not apply to the poorer institutions and not to the homes of the poor. It should be remembered that even substitute coal in Germany costs more marks than the indigent can afford.

I am obliged to Professors Möllers and Kayserling, to Dr. Helm, to Geheimrat Pütter, and many others for much information and the privilege of inspecting their institutions and statistics.

Berlin, Feb. 8th, 1921.

SERBIAN WORKERS REUNION.—The second annual reunion of the workers for Serbia will be held at the Wharncliffe Rooms, Great Central Hotel, London, on Tuesday, April 19th. Colonel Sir Courtauld Thomson, Chief Commissioner of the British Red Cross in the Near East from 1915 to 1919, will take the chair. Dinner 7 for 7.30 P.M., dancing at 9.30 P.M. Last year 164 were present, and it is hoped that all medical men and women who served with the medical missions or with the R.A.M.C. units attached to the Royal Serbian army will attend. Application for tickets should be made before April 12th to the honorary secretary, Miss Marx, 24, Melcombe-court, Dorset-square, London, N.W.1.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Professional Secrecy.

THE Council of the Royal College of Surgeons in Ireland has passed the following resolution:—

> The Council are of the opinion that it is contrary to the public interest that medical men should break their professional tradition and, without the consent of their patient, disclose information which they have obtained in the discharge of their professional duties. If any instance is reported to the Council in which one of the Fellows or Licentiates of this College is pressed to break confidence, such specific case will be considered by the Council and representations made to the authorities if such be thought necessary.

It is understood that an opinion in a similar sense has been embodied in a resolution by the Royal College of Physicians of Ireland.

Sentences on Medical Practitioners.

It is announced that Dr. Patrick McCarville, Monaghan, has been sentenced to six years' penal servitude for operating in a "Flying Squadron" in the Bragan Mountains. The trial took place at Belfast. The "flying party" occupied a house near the hills owned by a man named M'Kenna, in which arms, ammunition, and explosives were found. Dr. A. English, assistant medical officer of the Ballinasloe District Asylum, has been sentenced to nine months' imprisonment for having in her possession literature relating to Cumann n' Ban and Dail Earann.

The Irish Census.

Arrangements for the taking of the Irish Census were in train, and it was expected that the enumeration would be made next month. Last week, however, Dail Earann issued a decree prohibiting those who acknowledge its authority from assisting in the Census. In face of this very regrettable decision there is little use in the Commissioners proceeding with their task, since without cordial coöperation on the part of the entire public a Census will be worse than useless; it will be misleading.

March 28th.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Post-graduate Medical Teaching in Glasgow.

FOR many years post-graduate instruction in medicine has been given in several Glasgow hospitals, but only in the early part of 1914 was a special endeavour made to organise a permanent comprehensive post-graduate teaching scheme for Glasgow as a whole. The outbreak of war delayed further progress until 1919, when an emergency post-graduate course was organised and carried on in the summer and autumn. The course was highly successful, and the committee in charge felt justified in recommending the institution of a permanent scheme. Such a scheme was adopted on March 2nd, 1920, at a joint meeting of the Faculty of Medicine of the University of Glasgow and the General Committee for Post-Graduate Medical Teaching, which had been appointed in 1914 at a public meeting of the medical staffs of the various Glasgow teaching institutions and hospitals. The various teaching institutions and teachers taking part in the scheme constitute an association the business of which is managed by a Board elected periodically by them. The chairman of the Board is Sir Donald MacAlister and the vice-chairman Sir Hector C. Cameron. To inaugurate the scheme the Board arranged a series of weekly demonstrations for practitioners extending from November last till May of this year, and the number of practitioners taking advantage of the series is satisfactory. For the ensuing summer and autumn the Board has arranged a comprehensive course of instruction for medical practitioners extending from May till October. Most of the Glasgow hospitals are taking part in the scheme, which has been arranged as far as possible so that a practitioner who so desires may occupy the greater part of each day attending classes open to all qualifi medical practitioners and conducted independent of the undergraduate courses. A practitioner may en for one or several classes and may attend for one or mo months at his discretion. The Board has also had view the provision of facilities for young graduates a others who may wish to obtain a closer acquaintan with hospital work in one or other of its branches an who are prepared to give the necessary time. Arrangements have been made whereby a limited number ma become attached to wards or out-patient departments nominally as clinical assistants, for definite period throughout the year. As such they would work unde the direct supervision of the physician or surgeon i charge and carry out such detailed investigations as directed. A young graduate wishing to specialise in children's diseases, mental diseases, tuberculosis, venereal disease, or other subjects should find such a training invaluable. It has long been felt that Glasgow, in the midst of such a vast industrial population, with its abundance of clinical opportunities, should become one of the leading centres of post-graduate medical teaching. This year the Board of the Glasgow Post-Graduate Medical Association presents to the medical profession its first organised scheme of teaching, trusting it will enable practitioners to keep themselves abreast of the times. Full information concerning the classes and clinical assistantships may be had on written application to Dr. A. M. Kennedy, secretary, Post-Graduate Medical Association, University, Glasgow, or by applying personally at the various hospitals which are taking part in the scheme.

Coördination of Medical Services in Aberdeenshire.

A conference of representatives of the local authorities in the county of Aberdeen and other bodies interested in coördination of the medical services was held in Aberdeen on March 18th. The main points discussed were: The possibility of devising a scheme for coördination of the services of the medical staffs of the county council and the education authority with a view to economy in administration and prevention of overlapping; a possible agreement whereby the services of the nurses employed by the several district nursing associations be made available not only for the purposes of maternity and child-welfare schemes and the tuberculosis scheme but for the medical inspection and treatment scheme of the education authority. Could an agreement be arrived at between the education authority and the various local authorities not only for the cleansing of verminous children, but also, where necessary, of the whole household in which the children resided? The meeting was unanimously of opinion that a scheme of coördination for the several local authorities should be instituted. It was resolved that the county medical officer, the medical officers of health for the several burghs, the school medical officer, and the tuberculosis medical officer should consider the whole question of the coördination of the medical service and frame a scheme and submit it to a future meeting.

Perth Infirmary: Students' Effort.

A week's effort, organised by students of Dundee University on behalf of the Perth County and City Royal Infirmary, which last year had a deficit of almost £7000, was opened on March 26th by a free gift sale at Perth Auction Mart. The sale was opened by Sir Robert D. Moncrieffe. With donations the sum realised was fully £500.

Aberdeen Dispensary and Vaccine Institute: Annual Meeting.

The annual meeting of the managers and subscribers of the above institute was held on March 24th in the town-hall, Lord Provost Meff presiding. The annual report showed that in the past year the total number of cases treated in all departments was 3659, an increase of 417 on the previous year. The number of patients treated at their own homes by the general staff of the dispensary was 929, being an increase of 236 on the previous year, and the number of visits paid to patients was 2639, being an increase of 603. The number of vaccinations and revaccinations performed was 111.

being 72 more than the number for the previous year. The special ear, nose, and throat cases treated numbered 336, with a decrease of 19 over the number in the previous year. In the ophthalmic department 80 cases, and in the special department for women 142 cases, were treated. The number of prescriptions dispensed was 14,536, being 128 fewer than in the previous year. The number of medical students who paid for admission to the general practice of the institution was 100, being an increase of 74. The number of vaccination certificates issued amounted to 65, an increase of 27. The annual subscriptions received amount to £87 7*s.* 6*d.*, being a decrease of £6 13*s.* on the previous year. The total receipts for the year ending Dec. 31st, 1920, were £967 7*s.* 3½*d.*, and the total expenditure £1008 16*s.* 1½*d.*, leaving a deficiency for the year of £41 8*s.* 10*d.*

March 28th.

URBAN VITAL STATISTICS.

(Week ended March 19th, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18½ million persons, the annual rate of mortality, which had been 15·5, 15·2, and 15·2 in the three preceding weeks, declined to 13·9 per 1000. In London, with a population of 4½ million persons, the death-rate was 13·1, or 2·0 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 8·0 in Rotherham, 8·1 in Walsall, and 8·4 in Wallasey, to 23·7 in Dewsbury, 26·1 in Hastings, and 26·8 in Bury and in Tynemouth. The principal epidemic diseases caused 249 deaths, which corresponded to an annual rate of 0·7 per 1000, and comprised 77 from infantile diarrhœa, 63 from diphtheria, 51 from whooping-cough, 34 from measles, 20 from scarlet fever, and 4 from enteric fever. Measles caused a death-rate of 2·9 in West Bromwich and diphtheria of 2·8 in Merthyr Tydfil. The deaths from influenza, which had been 138, 167, and 149 in the three preceding weeks, numbered 151, and included 42 in London, 10 in Leicester, and 6 each in Birmingham and Sheffield. There were 3695 cases of scarlet fever and 2817 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 3730 and 2818 respectively at the end of the previous week. During the week ended March 12th 5 cases of encephalitis lethargica were notified in the County of London, and comprised 1 each in Finsbury, Greenwich, Lewisham, St. Marylebone, and Wandsworth. The causes of 44 of the 4946 deaths in the 96 towns were uncertified, of which 13 were registered in Birmingham, and 3 each in Stoke-on-Trent and Manchester.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 19·4, 18·0, and 18·5 in the three preceding weeks, fell to 17·8 per 1000. The 398 deaths in Glasgow corresponded to an annual rate of 18·9 per 1000, and included 47 from whooping-cough, 15 from influenza, 7 from infantile diarrhœa, 4 from diphtheria, 2 from scarlet fever, and 1 from measles. The 158 deaths in Edinburgh were equal to a rate of 18·5 per 1000, and included 7 from influenza, 6 from measles, 2 from whooping-cough, and 1 each from diphtheria and infantile diarrhœa.

Irish Towns.—The 140 deaths in Dublin corresponded to an annual rate of 17·3, or 0·8 per 1000 below that recorded in the previous week, and included 2 each from influenza and infantile diarrhœa, and 1 from diphtheria. The 147 deaths in Belfast were equal to a rate of 18·3 per 1000, and included 16 from whooping-cough and 3 from infantile diarrhœa.

(Week ended March 26th, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18¾ million persons, the annual rate of mortality, which had been 15·2, 15·2, and 13·9 in the three preceding weeks, further fell to 13·0 per 1000. In London, with a population of 4¾ million persons, the death-rate was 11·6, or 1·5 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 4·9 in Smethwick, 6·3 in Wallasey, and 7·0 in Gloucester, to 20·0 in Hastings, 20·5 in Middlesbrough, and 25·4 in Carlisle. The principal epidemic diseases caused 226 deaths, which corresponded to an annual rate of 0·6 per 1000, and comprised 65 from infantile diarrhœa, 59 from diphtheria, 53 from whooping-cough, 33 from measles, 14 from scarlet fever, and 2 from enteric fever. Whooping-cough caused a death-rate of 1·3 in Sunderland, and diphtheria of 1·4 in Tottenham and 2·8 in Dewsbury. The deaths from influenza, which had been 167, 149, and 151 in the three preceding weeks, declined to 121, and included 33 in London, 10 in Sheffield, 7 in Birmingham, and 6 in Leicester. There were 3608 cases of scarlet fever and 2778 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 3695 and 2817 respectively at the end of the previous week. During the week ended March 19th, 5 cases of encephalitis lethargica were notified in the County of London, and comprised 1 each in Islington, Finsbury, Bethnal Green, Battersea, and Wandsworth. The causes of 20 of the 4633 deaths in the 96 towns were uncertified, of which 4 were registered in London and 3 in Birmingham.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 18·0, 18.5, and 17·8 in the three preceding weeks, further fell to 15·3 per 1000. The 354 deaths in Glasgow corresponded to an annual rate of 16·8 per 1000, and included 19 from whooping-cough, 15 from influenza, 4 each from diphtheria and infantile diarrhœa, 2 from measles, and 1 from scarlet fever. The 115 deaths in Edinburgh were equal to a rate of 13·4 per 1000, and included 7 from influenza, 5 from whooping-cough, 3 from diphtheria, and 2 from measles.

Irish Towns.—The 136 deaths in Dublin corresponded to an annual rate of 16·8, or 0·5 per 1000 below that recorded in the previous week, and included 4 from infantile diarrhœa, 3 from influenza, and 1 each from whooping-cough and diphtheria. The 124 deaths in Belfast were equal to a rate of 15·4 per 1000, and included 7 from whooping-cough, 3 from infantile diarrhœa, 2 from measles, and 1 each from scarlet fever, diphtheria, and influenza.

The Services.

ROYAL NAVY MEDICAL CLUB: ANNUAL DINNER.

THE annual dinner of the Royal Navy Medical Club will take place at the Hotel Cecil, London, on Thursday, April 14th, at 7.30 P.M. for 8 P.M. Members who wish to be present are asked to inform the honorary secretary, Royal Navy Medical Club, 1, Lake Buildings, St. James's Park, London, S.W. 1, not later than seven clear days before that date.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lieut.-Cmdr. D. Loughlin is allowed to withdraw from the Service with gratuity.

ARMY MEDICAL SERVICE.

Major-Gen. O. R. A. Julian retires on retired pay.

ROYAL ARMY MEDICAL CORPS.

The undermentioned Captains relinquish the acting rank of Major: C. M. Gozney, G. D. Harding, and C. R. Dudgeon.

Lieut. (temp. Capt.) H. G. P. Armitage to be Captain.

H. W. Street, late Captain, Can. A.M.C., to be temporary Captain.

Officers relinquishing their commissions:—Temp. Major M. H. Allen (retains the rank of Major), Capt. E. Hulme and Temp. Capt. J. D. Judson (retain the rank of Captain).

TERRITORIAL FORCE.

Capts. H. K. Griffith and S. F. St. J. Steadman to be Majors.

ROYAL AIR FORCE.

Flight Lieut. C. W. T. Baldwin and Flying Officer F. T. Allen are granted temporary commissions in the ranks stated.

BRIGHTON, HOVE, AND PRESTON PROVIDENT DISPENSARY.—The report for 1920, submitted to the annual governors' meeting on March 15th, recorded increased charges to patients. The payments of members are to be increased from 2*d.* to 3*d.* for those over 16 years of age, and from 1*d.* to 1½*d.* per week for those under that age, the maternity fee being raised from £1 1*s.* to £1 11*s.* 6*d.* The whole of the members' contribution was paid to the doctors attending them without deduction of any kind, and the doctors supplied all necessary medicine free of any further charge. The administrative expenses were provided by subscriptions and donations and from the income of invested capital. The governors would in future be obliged to require those using the hospital to pay still further for some of the benefits they receive over and above their weekly subscription. The dispensary was founded in 1837 to enable the poorer classes to choose their own doctors and be attended to by their own paid medical men. When the National Insurance Act came into operation it was found that there was still need for the provident dispensary, 135 new members being admitted during 1920, against 156 in 1919. There has been some doubt expressed as to the effect on the work of the dispensary of Dr. J. F. Gordon Dill's provident scheme for hospital benefits and additional medical services, but this cannot yet be estimated.

"Audi alteram partem."

A CONTROLLED STUDY OF SANATORIUM RESULTS.

To the Editor of THE LANCET.

SIR,—I am glad that Dr. Thompson Campbell has replied to Dr. E. Ward's article on sanatorium results in your issue of March 12th. The obviously unscientific data on which Dr. Ward's conclusions are based must have struck many who read his article. If he were right, in our present state of knowledge, the best that can be done for tuberculous patients is to leave them alone. The worst, almost, is to send them to sanatoria for treatment. Statistics, as quoted by Dr. Ward, are of no value because they give figures which only deal with tuberculous cases from one, and that the least important aspect. To classify patients as suffering from slight, medium, and extensive tuberculosis is irrational and useless. In the ultimate issue it is not the extent but the intensity of the disease that tells. Slight disease with marked toxæmia has a far worse prognosis than extensive disease with a slight degree of toxæmia. Further, he does not state the duration of treatment. Three months in a sanatorium is rarely of much good, and, to judge the results of sanatorium measures from a series of cases who spend an inadequate period, is wrong. Many patients require three years' treatment and not three months. That it pays to keep patients for prolonged periods one has had frequent proofs. For example take the following case:—

One of our large Scottish Universities gives a prize to the student who proves to be the most brilliant man of his year in any faculty. Last year the man who obtained that prize was one who had been a patient in the Consumption Sanatoria of Scotland, Bridge of Weir, six years ago. He suffered from advanced phthisis and had very marked toxæmia. Had we discharged him at the end of one year, I have little doubt that he would have been dead within a few months. Had we discharged him at the end of two years, I fear that he would have survived but a short period. Keeping him for three years so established him that he was enabled to go through an arduous university course, and gain not only this coveted prize but a scholarship of several hundreds a year for four years. He has, I may say, had no recurrence of the symptoms during the period of strain. Dr. Ward says that "if a tree growing feebly in a poor soil is transplanted to a good soil, and then after improvement returned again to the bad soil, it will not resume its feeble growth, but will probably die." That is not quite true. It depends upon how long the transplanted tree is allowed to remain in the good soil.

Dr. Ward's controls seem to have been a doubtful collection. One of the reasons why they were not sent to sanatoria was because it was decided to keep them under observation for a while, to avoid for them the sanatorium stigma. Another reason was that they were unwilling to go to a sanatorium. What proof had he that they were really tuberculous? My experience in consulting and dispensary practice is, that patients, when diagnosed as tuberculous, are very submissive in their anxiety to be restored to health. They gladly acquiesce in any suggestion. Very rarely does the stigma of a sanatorium weigh with them. In cases that are doubtful it is different. The majority of these do well with a change and with symptomatic treatment.

A personal experience over many years has convinced one of the fact that in the sanatorium we have a means of dealing radically with this scourge in individuals. The results frequently are quite as dramatic as those obtained in the realm of surgery. Three things are required: the right type of case, a well-organised method of treatment along the lines of graduated rest and exercise, and a prolonged period of residence. Hyperaeration, hyperalimentation, and in selected cases tuberculin do the rest.—I am, Sir, yours faithfully,

JAMES CROCKET, M.D.,

March 21st. Lecturer on Tuberculosis, Glasgow University.

INSURANCE RECORDS: THE VIEW OF THE LONDON PANEL COMMITTEE.

To the Editor of THE LANCET.

SIR,—At their meeting on March 22nd the London Panel Committee directed me to send you a copy of the following resolutions:—

(a) That the Committee are of opinion that some form of medical record is necessary.

(b) That the Committee are of opinion that practitioners should not be required to enter matters on the record cards which in their opinion are likely to be detrimental to the interests of the insured persons concerned.

(c) That in the opinion of the London Panel Committee the present medical records are neither advantageous to the medical service nor beneficial to the community, and that it is desirable that they be discontinued forthwith.

I am, Sir, yours faithfully,

R. J. FARMAN,

Secretary, Panel Committee for the County of London.

Staple House, 51, Chancery-lane, W.C., March 24th, 1921.

THE FIGURES OF VENEREAL DISEASE.

To the Editor of THE LANCET.

SIR,—In your Parliamentary Intelligence of March 26th Lord Knutsford is reported to have made the following statement in the House of Lords:—

> "The figures of venereal disease in this country were almost too great to be believed. At the London Hospital alone they had 23,000 new cases last year. ......"

At a low computation each of these new cases would put in at least 12 attendances, so that the total number of attendances at the venereal department of that hospital would amount to considerably over a quarter of a million a year. As the total number of attendances at the department in 1919 was actually 24,499 Lord Knutsford was quite justified in his statement that "the figures of venereal disease in this country were almost too great to be believed." They most emphatically are. I am, Sir, yours faithfully,

Queen Anne-street, W., March 26th, 1921. J. ERNEST LANE.

"A VERY ENERGETIC PROPAGANDA."

To the Editor of THE LANCET.

SIR,—During the recent debate in the House of Lords on the report of the Special Committee on Venereal Diseases Viscount Knutsford urged the need of a "very energetic propaganda" directed towards the creation of a higher standard of morality and a lessening of the incidence of these diseases.

In this connexion a few figures as to the extent and scope of the propaganda undertaken in one year by the National Council for Combating Venereal Diseases may be of interest:—

Personal letters of inquiry received and answered by the medical department	33,000
Free pamphlets individually distributed, each pamphlet published or approved by the Ministry of Health and the N.C.C.V.D.	606,000

A very large number of addresses have been given to teachers, social organisations, employees of large firms and workshops, and to unselected audiences of the general public. It is impossible without special inquiry to estimate the numbers reached in this way by the 89 branches of the National Council, but the fact that one branch alone has reached 33,000 people during the last three months indicates the magnitude of this side of the work.

The cinematograph film has proved a most valuable addition to the propaganda material. Addresses have been given at exhibitions of approved films in more than 200 centres, the estimated number of such lectures being 718. Recent attendances at such displays as reported by local branches are: Gateshead (18 lectures), attendance 25,000; Plymouth (12 lectures), attendance 12,000; Leicester (24 lectures), attendance 23,000.

I am, Sir, yours faithfully,

E. O. GRANT,

Secretary, National Council for Combating Venereal Diseases.

March 26th, 1921.

THE DR. F. M. NEWTON FUND.

To the Editor of THE LANCET.

SIR,—Dr. Francis Morley Newton, medical officer of the Stoke-on-Trent Union Hospital, who died on Feb. 15th, 1920, left a widow and four children, aged 8, 7, 6, and 1½ years respectively. He suffered from asthma and diabetes and was unable to insure his life or to make provision in any other way for his family, so that their present financial position and future prospects are precarious. A fund in aid of the widow and children has been opened under a committee having for chairman Mr. R. H. Dickson, F.R.C.S. Irel., President of the North Staffordshire Medical Society, and Mr. W. Webster, F.R.C.S. Edin., as secretary.

Dr. Newton was educated at Epsom College and St. Bartholomew's Hospital. The committee feels that his friends or fellow students might wish to contribute to this fund, and takes the opportunity offered by your columns to reach them. Contributions will be gratefully acknowledged either by the chairman or secretary.

I am, Sir, yours faithfully,
WM. WEBSTER,
Secretary to the Fund.
64, King-street, Newcastle-under-Lyme, Staffs,
March 26th, 1921.

THE LABELLING OF THYROID TABLETS.

To the Editor of THE LANCET.

SIR,—We heartily support Dr. A. E. Carver's contention contained in his interesting letter in THE LANCET of March 12th on the prescribing of thyroid gland that the present slipshod method should be standardised. The dosage of all other widely used medicinal products is based on the dried substance, and why should an exception be made for thyroid gland? Would a pharmacist receiving a prescription for digitalis leaves assume for a minute that the doctor meant the moist as he did not state "exsic." or "desiccat.," and proceed to calculate how much of the dried powder he must dispense to be equivalent to the moist? What is absurd in the one case is equally absurd in the other. No doctor troubles himself about the ratio of dried product to moist for drugs other than thyroid. The system is purely a survival of a non-scientific basis.

Moreover, this mixed system is fraught with danger. For instance, a doctor prescribes 1 gr. of thyroid gland in tablet form and the pharmacist dispenses it, using, say, Jones's tablets, which are 1 gr. moist equivalent to 1/5 gr. dried substance. The patient now has a further supply, but from another pharmacist, who in this case, conforms to the B.P. standard and dispenses tablets which contain 1 gr. of the dried extract made by, say, Smith and Co. The patient finds a marked difference, it may be for the better or for the worse, and the doctor is puzzled. The prescriber never sees the bottle, and if he did most probably the issuing label would be covered by the pharmacist's dispensing label. We may add that in 1913 a paper was contributed from our laboratories to the Pharmaceutical Conference[1] using the argument which Dr. Carver now employs. Martindale and Squire, our two leading authorities after the B.P., both adopt the dried substance as their standard, and many of the leading manufacturers do the same.

Our experience does not conform with that of Messrs. Parke, Davis and Co. that prescribers mean "moist," for we made a large number of inquiries, and always had the same reply, that the "dried" substance was intended. In several cases the prescriber stated that the initial doses were always experimental and tentative, and the real dose required could only be decided by trial and result. We hope that this correspondence will do something to bring about a uniformity of prescribing and dispensing based on a more scientific and uniform principle.

We are, Sir, yours faithfully,
DUNCAN, FLOCKHART AND CO.
Edinburgh, March 22nd, 1921.

Obituary.

RUTHERFOORD JOHN PYE-SMITH, CH.M. SHEFF., F.R.C.S. ENG.,

EMERITUS PROFESSOR OF SURGERY IN THE UNIVERSITY OF SHEFFIELD, AND CONSULTING SURGEON, SHEFFIELD ROYAL HOSPITAL.

WE regret to learn the death of Rutherfoord John Pye-Smith, lately professor of surgery in the University of Sheffield, whose retirement from the medical profession only dates from a few months ago.

Rutherfoord Pye-Smith came of old Sheffield stock, his grandfather, John Pye-Smith, D.D., F.R.S., his father, Mr. Ebenezer Pye-Smith, F.R.C.S., being both Sheffield men, though the latter practised in London, where his third son was born in 1848. Like an elder brother, Philip, R. J. Pye-Smith was educated at Guy's Hospital, from which he qualified in 1872, becoming F.R.C.S. three years later. In 1876 he went to Sheffield as a general practitioner. He soon made his mark as a man of exceptional skill and versed in modern surgical procedure, which was at that date undergoing a revolution. He was appointed in 1877 honorary surgeon to the Public Hospital and Dispensary (now the Royal Hospital), where he became the pioneer of Listerism in the district, and as such quickly came into prominence. Younger men trained on the same lines soon appeared on the scene, but until his retirement Pye-Smith was always looked up to and respected as the doyen of surgery in Sheffield.

A colleague writes:—

When he began his career, like all other provincial surgeons of that time, he also carried on a general practice. In pre-Listerian days operative surgery alone was too scanty to provide a living, at any rate in the provinces, and it was necessary for surgeons to take general practice as well. Pye-Smith was almost the last of the local surgeons to do this, and he continued to do so more or less to the end of his career. As his surgical reputation grew and the amount of operative work demanded by the public increased, this combination of the two things made his work endless, and, as he could not bring himself to adopt modern labour-saving methods, it is difficult to understand how he got through his day's work. Motor-cars, typewriters, shorthand clerks—all these were anathema to him! For many years his single-horse brougham remained as the sole survivor of its kind amongst the profession! Every letter was in his own handwriting, and they were rarely less than four pages! No assistant prepared the patient for operation or put on the dressings after operation! Everything he did was done from beginning to end by himself. Perhaps the most striking tribute to his capacity for work, and his high sense of personal service, was the time which he devoted week by week to his hospital out-patients, even during the busiest part of his life. Four or five hours of his day, at least twice a week, would be given up to this part of his duties alone.

On the constitution of the University of Sheffield Pye-Smith was elected Professor of Surgery and gave long and valued services to the University, so that on retirement from his chair a few years ago he was rightly made Emeritus Professor, receiving also the honorary degree of M.Ch. in the University. In the affairs of the University, whether in the Faculty, Senate, or Council, he took an active part, rarely missing a meeting, while his frequent correction of the substance or the phraseology of the minutes or reports, of which he had always read every line, became a by-word amongst his colleagues. It was natural that he should be chosen to represent the University on the General Medical Council, where again his practical experience of the problems of education, learned in the evolution of the Sheffield Medical School, was often drawn upon by his colleagues.

During the war, though already showing distinct signs of strain from a life of incessant toil, he joined the staff of the Wharncliffe War Hospital, and in spite of remonstrances of friends, who saw how the work was telling upon him, he remained at his post until the conclusion of hostilities. But when the war was over he could not disguise from himself that his health was seriously affected, and a little less than two years ago he retired from practice and went to live in the country. He ceased work however too late, and although for a time his health improved he succumbed to a brief attack of influenza on March 23rd at his house in Ampthill.

Professor Pye-Smith, though closely associated in our minds with the University with which he was connected during his long working life, may be regarded as a general leader in surgery—he was one of the focuses from which modern surgery, based on the discoveries of Lister, was distributed throughout the country. Outside his profession he was keenly devoted to art, for music, painting, architecture, and beautiful scenery all had their appeal for him. His holidays were usually spent in walking tours in some part of his native country. His disposition was serene, no one ever saw him ruffled or impatient, and in the difficulties of others he was always ready to act as mediator. A religious man by conviction and in practice, he was a great supporter of Congregationalism in Sheffield. He was also chairman of the Council of the Y.M.C.A. in that city. He led a full, arduous, and generous life, and few citizens can ever have been more widely and more deservedly regretted.

Dr. Ernest Hasler Helby, medical officer to Princetown prison, was killed on March 24th by a fall from his motor-cycle. Dr. Helby was a Middlesex Hospital man who, after qualifying in 1893, demonstrated in bacteriology at King's College, London, before entering the prison medical service. He was at Birmingham and Aylesbury before he was appointed to Princetown.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

The Medical Committee of the House of Commons.

THIS Committee met on March 21st in Room 13, House of Commons, Dr. NATHAN RAW in the chair, when Sir PHILIP MAGNUS submitted correspondence with the Ministry of Health on the subject of security of tenure of medical officers of health. A Bill drafted some years ago (Public Health Officers Bill) was considered. Sir PHILIP MAGNUS agreed to have the Bill brought up to date and submitted to the committee at a subsequent meeting.

A deputation from the Medico-Political Union, consisting of Dr A. WELPLY, Dr. GORDON WARD, Dr. MACDONALD, and Dr. GREIG, was then heard. Dr. WARD submitted objections to the new medical record cards, and Dr. GREIG submitted objections to the new regulations of the Ministry of Health, to come into force next year, concerning the transfer of practices. A discussion then took place, when the deputation was promised that the points suggested would have the attention of the Committee.

HOUSE OF LORDS.

MONDAY, MARCH 21ST.

Criminal Law Amendment Bill.

On the motion of the Bishop of LONDON, the Criminal Law Amendment Bill was read a third time and passed.

WEDNESDAY, MARCH 23RD.

Danger of Smuggled Foreign Dogs.

Lord BLEDISLOE asked the Government whether there were good grounds for suspecting that during the last few months dogs had been smuggled into this country from abroad, thus evading the quarantine regulations and constituting a source of danger to the community in the matter of the transmission of hydrophobia; whether the maximum penalty for such evasion was for the first offence only £20; and whether seeing that such a fine, in the absence of any discretion on the part of the Court to substitute imprisonment therefor, was an insufficient deterrent to many such offenders, the Government would so amend the Diseases of Animals Act, 1894, as to empower the Court to impose in the case of a first offence the more drastic penalties provided thereby in the case of a second or subsequent offence. It seemed, he said, to be the fashion to breed as small a dog as possible of the varieties known as Pomeranians, Belgian griffons, Blenheim spaniels, and more particularly Pekingese, so that it was comparatively easy to smuggle into this country in a lady's muff, or in a small portable basket, dogs arriving across the Channel. There was also the danger, which was becoming a very real risk, of possibly larger dogs being transported to this country by aircraft, and more especially military aircraft. This suggestion was strengthened by the location of the various confirmed outbreaks of rabies, as published by the Ministry of Agriculture. During 1919 there were 155 confirmed cases of rabies, largely in the South and West of England, and more or less in the neighbourhood of the camps; and in 1920, although the number was considerably reduced, no more than 42 outbreaks having taken place, much more than half those were in Wiltshire, which, of course, comprised Salisbury Plain, and in the three adjacent counties. Only five took place in all the rest of England. In the early part of this year the Army Council issued an instruction prohibiting the embarkation of any dogs with soldiers on transports or upon other means of conveyance to this country without a licence from the Minister of Agriculture. In the meantime, however, harm seemed to have been done by this illegal smuggling. A month ago the Masters of the Foxhounds Association passed a unanimous resolution urging the Government to take steps against this illicit importation of possibly diseased animals. A rabid dog was very seldom found wearing a muzzle, and it was therefore questionable whether muzzling, carried out sporadically in certain areas only, was an effective preventive of the spread of rabies.

Lord WILLOUGHBY DE BROKE, in supporting what Lord Bledisloe had said, remarked that not long ago a whole pack of foxhounds had to be destroyed. It seemed to him that lovers of Pekingese and Belgian griffons and such dogs appeared to lose all sense of public spirit in this regard, and it would be a great advantage if the Minister of Health would look into this matter and offer some kind of advice to the public against these dogs being allowed to lick dishes and plates in public restaurants as he had seen them do.

The Earl of CRAWFORD (Chancellor of the Duchy of Lancaster) said, with regard to the danger of smuggling dogs into the country by aircraft, he was informed that the Department of Agriculture, which had given the closest attention to the subject, had made inquiries and had satisfied itself that public aerodromes were now very well watched. The Department, however, was quite conscious that some smuggling might be attempted, and they were taking steps, which he would not particularise or describe, to reduce that danger to a minimum. As regarded fresh legislation, for the time being at any rate, the Board of Agriculture was of opinion that the present penalties, the danger of the quarantine, the guard of the Customs, and so forth, could be relied upon to keep disease out of the country; but if any evidence were forthcoming of fresh attempts to use the aeroplane for this specific purpose, the Ministry would be quite prepared to ask for increased penalties.

HOUSE OF COMMONS.

TUESDAY, MARCH 22ND.

Army Veterinary Service.

Sir L. WORTHINGTON-EVANS (Secretary for War) informed Colonel Sir A. HOLBROOK that the question of the amalgamation of the Army Veterinary Service with the Remount Service was not a new one. He was informed that it would not be practicable for the Army Veterinary Service to perform the duties of the Remount Service in addition to their own duties, and it was not considered that a saving would accrue from a combination of the two services even if this were feasible.

WEDNESDAY, MARCH 23RD.

Government's Opium Policy.

Mr. MONTAGU (Secretary for India) informed Sir J. D. REES and others that it was not proposed to make any change in the opium policy of the Government of India as a result of the recrudescence of poppy cultivation in China. The matter was now governed by the Hague Convention. Under that Convention, as China had prohibited the import of opium, India was bound to prevent the export of Indian opium to China. He was given to understand that the matter would be discussed by the Opium Advisory Committee of the League of Nations at the forthcoming Congress at Geneva.

Sanitary Arrangements of Caravans.

Major GLYN asked the Minister of Health what powers were possessed by the Ministry of Health to control the conditions and sanitary arrangements of caravans, especially when these had ceased to be really mobile and had settled in some field or vacant piece of land, joined shelters to the vans, and, without control or method, established a kind of encampment of vehicles, often a menace to the health of a district.—Dr. ADDISON replied: The Ministry of Health have themselves no direct power in this matter, but the local authority can take action under the Nuisances Provisions of the Public Health Act where a tent, van, shed, or similar structure is in such a state as to be a nuisance or injurious to health, or is so overcrowded as to be injurious to the health of the inmates. The local authority can also make by-laws under Section 9 of the Housing of the Working Classes Act, 1885, for promoting cleanliness in, and the habitable condition of, such structures, and for the prevention of nuisances in connexion with them.

Venereal Disease.

Captain ELLIOT asked the Minister of Health whether he had at any time sanctioned the provision of public money, either out of the National Exchequer or out of local revenues, for the purposes of the National Council for Combating Venereal Diseases, either for the purpose of advertisement or for any other purpose; and, if so, whether he would specify what amount of money had been so provided in each of the financial years affected and on what purposes the money had been spent.—Dr. ADDISON replied: The reply to the first part of the question is in the affirmative. In accordance with the recommendation of the Royal Commission on Venereal Diseases the National Council for Combating Venereal Diseases has been recognised by the Government since 1916 as the authoritative body for the purpose of spreading knowledge and giving advice in regard to the question of venereal diseases in its varied aspects. During the years ended March 31st, 1919, and March 31st, 1920, grants were made to the National Council from the Exchequer amounting to £13,000 and £15,600 respectively, and the grant up to date during the current financial year amounts to £13,750. These grants have been paid in respect of expenditure incurred by the National Council in connexion with a campaign of publicity and education by means of lectures, meetings, exhibitions, and press advertisements, and by pamphlets, posters, and other literature. The grants for the current financial year and for 1919-20 included a proportionate sum for administrative expenditure. No grants are made direct by local authorities to the National Council, but some of these authorities have made contributions to local branches of the Council in aid of the propaganda and educational measures undertaken by those branches.

Captain ELLIOT: In view of the recent recommendations of the Birth Rate Commission will the right honourable gentleman see that steps are taken to persuade the two societies engaged in the campaign against venereal disease to coöperate instead of pulling in different directions?—Sir J. D. REES: Will the right honourable gentleman in this matter regard with suspicion reports of a profession which has reported that victorious England has a C 3 population?—Dr. ADDISON: I cannot agree with these generalisations. I have done everything I can to get these two different bodies to work together and am continuing to do so.

Infant Mortality in London.

Mr. GILBERT asked the Minister of Health what had been the rate of infant mortality during the last four years in London, and what had been the cost on the rates during the same period of maternity and child welfare centres established in the London area.—Dr. ADDISON replied: The rate of infant mortality in London has fallen during the last four years as follows: 1917, 104; 1918, 108; 1919, 85; and 1920, 75. The average cost to the rates of London of the Maternity and Child Welfare Service was during each of the last four years considerably less than 1d. per £ of assessable value.

Death-rate from Phthisis and Tuberculosis.

Captain ELLIOT asked the Minister of Health the number of deaths and the death-rate per 1000 from phthisis and tuberculosis, all forms, in 1920, and similar figures for the previous five years; and whether, as a measure of public economy, he proposed to reduce the number of sanatoriums and beds available for coping with this disease.—Dr. ADDISON replied: The total deaths during the past six years from 1915-20 inclusive from all forms of tuberculosis were as follows: 54,295, 53,858, 55,934, 58,073, 46,312, 42,545. The death-rates per 100,000 of the population for the same years were as follows: 151·5, 152·9, 162·4, 169·4, 125·8, 112·8. As I have already stated, the figures for the last two years were the most encouraging we have had since the inception of the national scheme for the treatment of tuberculosis. The answer to the last part of the question is in the negative.

Grants for Tuberculosis, Maternity, and Venereal Disease.

Mr. BRIANT asked the Minister of Health what were the grants towards the services for tuberculosis, maternity welfare, and venereal disease for London during the last year; and if there had been any reduction in infant mortality since the grants in aid were issued.—Dr. ADDISON replied: The grants paid to local authorities in London during the last completed financial year in respect of the services mentioned were: tuberculosis, £49,195; maternity and child welfare, £39,763; venereal disease, £35,543; total, £124,501. The mortality-rates are given in my reply to the honourable Member for Central Southwark. The total expenditure in all these services combined out of an average rate in London of 14*s.* 5*d.* for the year 1920-21 was 2¼*d.*

Birth-, Death-, and Marriage-rates in Ireland.

Lieutenant-Colonel ALLEN asked the Chief Secretary to the Lord Lieutenant of Ireland the birth-, death-, and marriage-rates, respectively, in Ireland for the years 1910, 1914, and 1920.—Sir H. GREENWOOD replied: The figures per 1000 of the population are as follows:—1910: marriages 5·04, births 23·3, deaths 17·1; 1914: marriages 5·41; births 22·6, deaths 16·3; 1920: marriages 6·18, births 22·2, deaths 14·9.

Washington Maternity Convention.

Mr. CLYNES asked the Prime Minister whether, in view of the great importance of the Washington convention on maternity, and also of the widespread opinion that the draft conventions of the Washington conference must be submitted to Parliament, an opportunity would be given after Easter to discuss the Government's policy on the maternity convention, and also the Ministerial declaration that it was for the Government to decide whether any particular convention should be submitted to Parliament.—Mr. LLOYD GEORGE (Prime Minister) replied: I would refer my right honourable friend to a reply given on Feb. 22nd in which a promise was given by my right honourable friend the Member for the Central Division of Glasgow to the effect that consideration would be given to this subject in the event of a question being put after Easter.

Condensed Milk Standard.

Mr. GRATTAN DOYLE asked the Minister of Health whether he was aware that the draft regulations based on the Committee's recommendations for a standard of condensed milk were at direct variance with the bulk of the evidence submitted by interests concerned; and whether the Committee's report and recommendations would be published.—Dr. ADDISON replied: I understand that the standards recommended by the Committee are not substantially different from those which were advocated by the majority of trade witnesses except in the case of one variety (full cream unsweetened) where a somewhat lower standard has been adopted. I am prepared to publish the Committee's report if there is any general desire to that effect.

Nation's Supply of Potable Water.

Major KELLEY asked the Minister of Health whether he had received any recommendations for the conservation and allocation of the nation's supplies of potable water; and whether he proposed to take action to reserve sources of water-supply for towns such as Rotherham, whose populations were certain to expand greatly, but whose areas did not adjoin any watershed unpolluted by industry or agriculture.—Dr. ADDISON replied: Recommendations on the subjects contained in the first part of the question are made in the Second Interim Report of the Water Power Resources Committee (Cmd. 79). These have been under my consideration, but it is not practicable to propose legislation on the subject at present.

Pre-war Naval Disability Pensioners.

Lieutenant-Colonel ARTHUR MURRAY asked the Secretary to the Admiralty whether naval officers who were invalided out of the service before the war, but who served during the war, were to be included amongst the pre-war disability pensioners.—Sir J. CRAIG (Parliamentary Secretary to the Admiralty): The answer is in the negative.

Coroners Remuneration Bill.

Major STEEL asked the Prime Minister whether he would give facilities for the second reading and subsequent stages of the Coroners (Remuneration) Bill in order that this Bill might be passed quickly into law.—Mr. LLOYD GEORGE replied: The Government do not oppose the second reading of this Bill, but it must take its chance with other private Bills.

BRITISH ASSOCIATION.—The next meeting is announced to take place at Edinburgh from Sept. 7th-14th. On the evening of the opening day Sir Edward Thorpe will deliver his presidential address. Sir J. Frazer is to preside over the section of Anthropology, Sir Walter Fletcher over that of Physiology, and Professor C. Lloyd Morgan over that of Psychology. Biochemistry, Vocational Tests, and the Relation of Genetics to Agriculture are to receive their share of attention.

LONDON TEMPERANCE HOSPITAL.—An entertainment, including a musical programme and amateur theatricals will be given by the nursing staff of this institution on April 13th, 14th, and 16th at 8 P.M. The entertainment is in aid of the building fund and will be held in the out-patient hall of the hospital. The prices of admission to reserved seats are 10*s.* 6*d.*, 5*s.*, 2*s.* 6*d.*, and 1*s.* Tickets can be obtained from the matron at the hospital.

Medical News.

UNIVERSITY OF CAMBRIDGE: DIPLOMA OF PSYCHOLOGICAL MEDICINE.—A five weeks' revision course for the diploma examination will be held in Cambridge from July 18th to August 20th. The course will include lectures and laboratory work on the Anatomy and Physiology of the Nervous System (Dr. C. R. A. Thacker), and on Psychology (Dr. J. P. Lawson) for Part I. of the examination, and lectures and clinical work on Psychopathology (Dr. C. S. Myers and Dr. J. F. E. Prideaux) and Mental Diseases (Dr. M. A. Archdale) for Part II. The fee for the whole course is 12 guineas. That for the course for Part I. or Part II. alone is 6 guineas. The examination for Part I. (Anatomy and Physiology of the Nervous System, and Psychology) is held in October, and that for Part II. (Neurology and Psychiatry) in December. Further information may be obtained from the Secretary to the D.P.M. Committee, Psychological Laboratory, Downing-street, Cambridge.

UNIVERSITY OF LEEDS.—Dr. R. J. Stewart McDowall, whose appointment to the University lectureship in experimental physiology and experimental pharmacology was noted last week, was in 1917 specialist sanitary officer in charge of the Palestine water-supplies, which included the pipe line across the Sinai Desert, and was later deputy assistant director of medical services for the British Forces in Palestine, Syria, and Cilicia. Since demobilisation he worked under Sir E. Sharpey Schafer in the physiology department of the University of Edinburgh, surrendering the positions of lecturer in that department and of clinical tutor in medicine at the Royal Infirmary under Sir Robert Philip to come to Leeds. He was a member of the International Congress of Physiology held in Paris last year and is on the general and organising committee of the physiology section of the British Association.

UNIVERSITY OF LIVERPOOL.—At examinations held recently the following candidates were successful:—

DEGREE OF M.D.

Amy Hodgson and N. W. Walmsley.

FINAL EXAMINATION FOR DEGREES OF M.B., CH.B.

Part III.—Eileen Dowling, F. H. Edwards, S. Farris, W. S. Gilmour, H. T. Hughes, R. M. Jones, Florence M. Lamport, R. F. J. Martin, F. G. Pailthorpe, J. H. Pottinger, A. McK. Reid, and J. C. Twomey.

Part II.—G. C. Bhatia, Eleanor E. Briant, H. R. Chibber (distinction in Forensic Medicine and Toxicology), and C. Cookson.

Part I.—Ethel Ashton, H. R. Chibber, G. Clark, H. M. Cohen, R. W. Cowie, J. Elsohn, I. S. Fox, H. S. Gordon, R. C. Gubbins, W. D. Jeans, T. Knowles, Mary E. Nosworthy, G. Sanders, S. G. Sheir, Mary D. H. Sheridan, W. T. de V. Thomson, Mary G. T. Williams, and D. A. Woodeson.

Honours, Class II.—J. G. L. Jones (distinction in Obstetrics).

DIPLOMA IN PUBLIC HEALTH.

A. J. Hawes, J. O. Murray, and L. B. Stott.

DIPLOMA IN TROPICAL MEDICINE.

R. Nixon, A. S. Richmond, J. M. Skinner, R. B. Stewart, and Marion Thomson.

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.

C. C. Anderson, J. H. Mather, R. E. Roberts, and R. I. C. Rodgers.

UNIVERSITY OF ABERDEEN.—The following candidates have passed the Final Professional Examination in Medicine:—

Charles Davidson Allan, John James Hall Anderson, Nicholas C. Bodenstein, Foong K. Chen, John Craig, Lilian Fyfe Gall, Ronald K. Grant, G. W. Hay, Eleanora M. P. Law, Margaret Lipp, Matthew H. Logg, Douglas R. Macdonald, Alexander McKay, Elsie Mackie, Katherina F. E. van der Merwe, Mary G. Milne, Dorothy Mitchell, John I. Moir, Marian Elizabeth Mowat, J. M. H. Murray, Janet Cruickshank Nicol, Mary Milne Pyper, Alexander E. Reid, Edwin N. D. Repper, James P. J. Rossouw, George Saint, Norman Charles Simpson, G. Violet G. Smith, Ian R. Spark, Alexander L. G. Thomson, Ian S. Thomson, and A. R. Wood.

WORK OF THE CITY CORONER DURING 1920.—Dr. F. J. Waldo, J.P., H.M. City coroner, held during the year 1920 599 inquiries in the City of London, including H.M. prison at Holloway, as well as in Southwark. Post-mortem examinations were ordered and carried out in all but 14 inquests of death. Juries were summoned in all cases except those of a few natural deaths; Dr. Waldo maintains this constitutional and popular pre-war method on the principle that the coöperation of an intelligent jury, such as can be found in the City, secures a better and more satisfactory tribunal than that constituted by a coroner sitting alone. Among the inquests held were two cases of murder, 2 of manslaughter, 1 of justifiable homicide, 1 of felo-de-se, 22 of suicide, and 1 of arson. Inquests were held on 24 children under the age of 1 year and on 52 between the ages of 1 and 16 years. Fifty-eight fatalities (28 in the City, 30 in Southwark) were due to vehicles. Dr. Waldo, backed by his juries, has made frequent appeals to the Minister of Transport, the Home Secretary and Police, the London County Council, and the various local road authorities for more street refuges, more police at fixed crossings to assist foot-passengers across congested streets, and compulsory side life-guards on all heavy commercial motors, similar to those in use on motor omnibuses; but his recommendations have so far met with little notice. An inquest was held on the body of one infant accidentally suffocated whilst in bed with the parents, this figure being the lowest ever recorded. The marked general decrease throughout England and Wales during the past few years in this class of preventable death has, in the coroner's opinion, much less to do with the question of drink than with the more general use of cots and cradles. The holding of more autopsies has been an important factor in the lessening in the number of these deaths. Inquests were held in only 8 cases (3 in the City, 5 in Southwark) of sudden death accelerated by the administration of anæsthetics for surgical operations. As heretofore, the deaths occurred during the use of chloroform or a mixture containing chloroform.

NORTH-EAST LONDON POST-GRADUATE COLLEGE.—A special post-graduate course is to be held from Monday, April 25th, to Saturday, May 7th, inclusive. At 10.30 A.M. and 11.45 A.M. each day practical demonstrations will be given on the more important clinical and laboratory methods applicable in medical practice. In the afternoons at 2 P.M. demonstrations will be given on groups of cases illustrating special subjects, and at 3 P.M. on selected cases in various departments of practice. At 4.30 P.M. each day there will be either a clinical lecture (free to qualified medical practitioners) to be delivered by Sir William Hale-White, Sir Thomas Oliver, Sir Henry Gauvain, Mr. H. D. Gillies, Dr. P. Manson-Bahr, Dr. Frederic Thomson, and others, or clinical consultations on obscure medical and surgical cases. On Saturdays demonstrations will be given on the Early Diagnosis of the Infectious Fevers at the North-Eastern Fever Hospital, St. Ann's-road, London, N., and on cases of Insanity Associated with Epilepsy at the L.C.C. Mental Hospital, New Southgate, London, N. Further information and syllabus of the course may be obtained from the Dean of the College at the Prince of Wales's General Hospital, Tottenham, N. 15.

HORSHAM COTTAGE HOSPITAL.—The governors of the Horsham Cottage Hospital have found it incumbent upon them to increase the fees of the patients rather than let the institution run into serious debt. Increased expenditure consequent upon high prices has not been met by a corresponding increase in the receipts, and at the twenty-ninth annual meeting held on March 23rd it was unanimously agreed that each patient should pay such weekly contribution as the committee may fix, not being less than 7*s.* 6*d.* or more than £2 2*s.*, the committee still holding the power to remit the whole or part of such payment at its discretion; and that the minimum fee for private patients be £5 5*s.* per week, in addition to dressings, extras ordered by the doctor, and a special nurse or nurses, should such be required. There were 228 patients admitted during the year, including 30 accident cases; 100 major operations and 204 minor operations were performed. The number of patients (228) was the highest on record. Although the governors have some £10,000 in hand for the enlargement of the hospital it has been decided that the building scheme must remain in abeyance owing to the high cost of materials and labour.

THE LATE DR. J. D. KENNY.—John Drought Kenny, whose death occurred on March 9th at his residence, The Grange, Wickersley, near Rotherham, was a native of Ireland, and obtained his medical education at Queen's College, Galway, and at the Ledwick School and Adelaide Hospital, Dublin. At the Ledwick School he was first prizeman in practice of medicine. He qualified in 1884, and in 1887 went to Yorkshire, where, after acting for some time as assistant to the late Dr. Lyth, of Rotherham, he settled down in practice in the village of Treeton, where he remained for the next 25 years. He soon built up a large practice, gaining the esteem and affection of all classes by his good nature and devotion to work, and he will long be remembered by the poor of the village for the help he gave them in money and provisions during a long and serious coal strike. His patients and friends showed their appreciation by presenting him with a motor-car when in 1912 he left them to take up practice in Wickersley. He held numerous appointments under the guardians, the Yorkshire Coal-owners Indemnity Company, and various colliery companies, and he also took much interest in ambulance work; for his services in the latter connexion he was made, in 1911, an honorary associate of the Order of St. John of Jerusalem. His death occurred from pneumonia after a illness, and came as a great shock to his He is survived by his widow.

SUMMER TIME, 1921.—The Home Secretary has fixed summer time this year to commence on Sunday, April 3rd, at 2 to 3 A.M.

GENERAL HOSPITAL, BIRMINGHAM.—The annual meeting was held on March 16th, under the presidency of the Bishop of Birmingham. The report stated that the main difficulties to be faced were lack of funds and of accommodation. The ordinary subscriptions and donations showed a steady increase and several large and unexpected donations had been received. In December the National Relief Fund made a donation of £17,800 towards that part of the debt contracted owing to war conditions, and this, added to the £40,014 obtained by the sale of securities, enabled the hospital to be temporarily free from debt. But such additions to the funds could not be expected in the future, and without other sources of income the hospital must sell further securities or greatly reduce its work. The average cost of each in-patient was £9 9*s.* 11*d.*, as compared with £7 11*s.* 7*d.* for the previous year. The total expenditure was £93,734 and the receipts £63,599, an excess of expenditure over income of £30,135. These figures are exclusive of the sums received from the National Relief Fund and from the sale of securities. The hospital had received £9000 from the Hospital Saturday Fund, as compared with £6000 last year, in addition to a grant of £1000 for the Jaffray Hospital. From the Hospital Sunday Fund was received a sum of £2834, an increase of £822 on last year. The number of in-patients was 6930, an increase of 486. The daily average number in hospital was 335, an increase of 20 on the average of the last five years. The out-patients numbered 42,376, as against 39,330 in 1919; 5923 operations were performed during the year.

Medical Diary.

SOCIETIES.

BIRMINGHAM MEDICAL PSYCHOLOGICAL SOCIETY.

WEDNESDAY, April 6th.—4.15 P.M., Paper:—Dr. R. M. Ladell: Some Problems in the Treatment of Pensioners.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

Births, Marriages, and Deaths.

BIRTHS.

ASH.—On March 26th, at Crowborough House, Crowborough, Sussex, the wife of Richard Guy Ash, L.D.S.R.C.S. Eng, of a daughter.

FRANKAU.—On March 24th, at Wyndham-place, W., the wife of Claude Frankau, C.B.E., D.S.O., F.R.C.S., of a son.

GROVE WHITE.—On March 23rd, at Gledhow-gardens, South Kensington, the wife of Captain J. H. Grove White, I.M.S. (retired), of a son.

LESCHER.—On the 25th March, at 48, Kedleston-road, Derby, to Bridget, wife of Dr. Frank Graham Lescher, M.C., B.A., M.B. Cantab., a daughter—Bridget Mary.

DEATHS.

PYE-SMITH.—Rutherfoord John Pye-Smith, J.P., F.R.C.S., late of Sheffield, on the 23rd March, at his house in Ampthill, Beds., after three days' illness. Aged 73. Funeral 29th, 2.30, at Ampthill.

SHAW.—On March 17th, suddenly, Lawrence Drew Shaw, D.S.O., M.B., Ch.B., Harley-street, London, W., and late of Tientsin, China.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Communications, Letters, &c., to the Editor have been received from—

A.—Dr. E. E. Atkin, Lond.; Dr. H. el Arculli, Liverpool; Dr. G. Alexander, Furness; Automatic and Electric Furnaces, Ltd., Lond., Managing Director of; Dr. E. D. Adrian, Cambridge.

B.—Dr. G. R. Bruce, Jarrow-on-Tyne; Brooklyn Cardiological Society; Dr. J. Blomfield, Lond.; Mrs. C. Brereton, Lond.; Prof. H. Briggs, Liverpool.

Notes, Short Comments, and Answers to Correspondents.

OBSERVATIONS ON SOME OF THE DISEASES OF ANIMALS COMMUNICABLE TO MAN.[1]

BY FREDERICK HOBDAY, C.M.G., F.R.C.V.S., F.R.S.E.,
HONORARY VETERINARY SURGEON TO H.M. THE KING; FORMERLY PROFESSOR OF THERAPEUTICS AND HYGIENE IN THE ROYAL VETERINARY COLLEGE, LONDON.

STUDENTS of human medicine have nowadays become specialists and subdivided specialists, and students of veterinary medicine have done the same, but there is still room for further specialism—that is, for those who will bridge the gap which divides the two, and specialise in comparative medicine; by which I mean the study of the analogies and differences shown in diseases intercommunicable between men and the various species of animals which, having no thought for the future, only live (some of them very short lives) to look forward to a meal, to automatic sleep, and to the excitement of an occasional fight or love affair.

By the study of comparative medicine our sphere of knowledge may be greatly enlarged, and by comparison of symptomatology, of the sites especially affected, of immunity and susceptibility we shall progress forward more rapidly in the fight against disease, and investigators will often save themselves much of the time at present lost in following unnecessary side-tracks. Knowledge of the fact that certain species of animals are refractory, or even completely immune, to certain diseases is also of enormous value and must always have a satisfactory explanation, if only the latter can be discovered. There is no better illustration of such immunity than that of the ox tribe to the disease known as glanders. Why should the ox be immune to glanders when the horse, ass, mule, certain carnivora, and man fall easy victims? A knowledge of the diseases of animals communicable to man cannot but be beneficial to the worker in human pathology; and the number of diseases concerned is astonishing. The comparative aspect of any one of them could be made the subject of a separate paper, but my intention here is to generalise, and to introduce the names of certain diseases met with in Great Britain, communicable from animals to man, with the object of drawing attention to the great value of a knowledge of the comparative aspect of each; and, in order to attain that knowledge, the necessity for collaboration and coöperation between the medical and veterinary professions.

I am sure that individual experiences of others will add emphasis to the above remarks, and will perhaps form the basis of some scheme advantageous to both medical and veterinary practice.

Communicable Diseases.

We have at the present time, in Great Britain at least, the following which are indisputably communicable: glanders, anthrax, tuberculosis, rabies, foot-and-mouth disease, mange of all animals (horse, ox, camel, dog, cat), ringworm (especially of horse, calf, cat, and mouse), certain forms of seborrhœa (such as farriers get from handling horses with greasy legs); and I think that the great prevalence of pyorrhœa in pet dogs (which are often kissed and allowed to lick the lips and hands of their owners) should be regarded as a possible contributive factor towards that disease in human beings; pyorrhœa may at some future date be definitely added to the list.

Others, produced by parasites which require an animal host in order to make their life-cycle complete before they can become pathogenic to man, are *Echinococcus*, the *Cysticercus bovis* (the larval stage of the *Tænia saginata* of man), and *Cysticercus cellulosæ* (the larval stage of *Tænia solium*), the parasites of measly beef and measly pork respectively, and the *Trichina spiralis* of the muscles of the pig, which gives rise in countries where ham is largely eaten smoked and not necessarily cooked, to trichinosis in man.

I now propose briefly to take each condition in turn and consider the most important points affecting both man and the lower animal, and discuss how the veterinary surgeon can help his medical confrère. I would particularly emphasise a careful consideration of glanders, anthrax, rabies, foot and mouth disease, and certain forms of mange and ringworm, as their only source is from some species of animal, and when we of the veterinary world have stamped out these diseases completely from our patients they will automatically cease to exist in man; the attainment of this result cannot but add credit to the study of comparative medicine.

Tuberculosis stands in a category by itself, as not only is it contagious from man to man, animal to animal, and animal to man, but it also does its work insidiously through milk, which is so necessary as a food for children; and even when the animal is dead its meat is still dangerous, being still, in many instances, only perfunctorily inspected. It is to our shame to have to admit how backward England is in this matter.

Glanders.

Glanders is a particularly good disease with which to begin the list, as when it is eliminated from the veterinary schedule it will become unknown as a disease of mankind. Even now a medical man is frequently puzzled when confronted with a patient suffering from this infection, so rarely is it seen; but the veterinary surgeon, with the aid of mallein, can almost invariably make his diagnosis with certainty and within 48 hours. Here the veterinary profession has to lead the way, and that it is doing its duty in this respect is shown by the fact that in 1901 (only 20 years ago) some 2370 horses were destroyed for glanders in Great Britain (1828 of these coming from London), and that the present statistics of the Veterinary Department of the Ministry of Agriculture show that during the past year (1920) only 15 outbreaks occurred in the whole of the British Isles, with a total destruction of only 22 animals; and this, too, after the sale of some 150,000 army horses and mules gathered together from various countries and employed in the war. In mallein we have a sure diagnostic test; by its use glanders was kept completely under control amongst the British horses and mules during the recent war; I believe I am correct in saying that during that time no case of glanders in man was ever reported; whereas, during the South African campaign, glanders was terribly rife amongst animals and caused endless anxiety both to veterinary and medical officers.

Some 15 or 20 years ago, in the districts of London which contained large cab and omnibus stables it was a rare thing for a County Council veterinary inspector to have a day go by without being called in to see a suspected case of glanders, and I recollect one stud of only about 2000 horses from which some 90 glandered were taken within 12 months. Mallein was then in its trial stage, and the law did not enforce its compulsory use on the in-contact cases, the consequence being that when the owner of the stable had an outbreak of glanders he promptly sent the in-contact animals to a repository, and thus disseminated the disease broadcast. Twice I have officially been present at the post-mortem examination of men who had died of the disease, and in neither case was the disease suspected until just before death, one being treated for pleurisy and the other for rheumatism.

At the present time the use of mallein is compulsorily applied by law to all ponies before they are sent underground for colliery work. When an outbreak takes place in a stud or stable in any part of the British Isles the whole of the "in-contacts" are immediately quarantined and tested. All reactors are destroyed, all suspects set aside and retested until the veterinary inspector is satisfied that a clean certificate can be given to the stud.

During the late war special precautions were taken by the officers of the Royal Army Veterinary Corps to isolate and mallein all animals on purchase and again on admission to and evacuation from veterinary hospitals. All units were malleined at regular intervals, and before being finally sold, either for work or human food, all animals were submitted to this test. In this way millions of doses were used, but the result justified the trouble taken, and no army of the whole Allied force was so free from glanders as ours. The infection is usually transmitted to man from a glandered horse, ass, or mule by means of nasal discharge, discharge from a farcy bud, or contact of an abraded surface with a sponge, brush, or stable utensil which has become contaminated with some of the infectious discharge from the animal. The possibility of infection of man by ingestion also was drawn attention to by the late Mr. W. Hunting, the chief veterinary inspector of the London County Council, who observed men handling the nostrils of infected horses and then eating their bread-and-meat or bread-and-cheese without washing their hands. The men most commonly affected are those whose life brings them into contact with horses, and one has only to read the medical press to see the hopelessness of treatment when once the disease has become established.

I believe I am correct when I say that there is only one instance on record where a human patient has survived and permanently become clear of a glanders infection, the fortunate man being a well-known member of my own profession, but it was only after endless operations and several years of painful treatment that his medical advisers were able to certify a cure. One of those who died of this disease last year was a veterinary bacteriologist of the Government of India, a man of great promise, the disease being contracted during the course of his duty.

---

[1] An illustrated lecture delivered (Feb. 3rd, 1921) before a combined meeting of the Royal Society of Medicine and the Central Branch of the National Veterinary Association.

Glanders in carnivorous animals has been observed in lions fed in a zoological garden on infected horseflesh which was given raw.

It is gratifying to read in the annual report of Sir Stewart Stockman, the chief veterinary officer of the Ministry of Agriculture, that "this disease is now approaching the point of eradication." When that is accomplished in horses there will also be one less disease for the human race to fear.

Anthrax.

Anthrax still takes its toll of both animal and man, being met with in the latter principally amongst those who have to deal with animal products, such as skin, hair, wool, and hides from abroad, and those who make or assist at post-mortem examinations of dead animals. Mention of infected Japanese shaving brushes, which have lately been referred to in the medical and lay press, must not be omitted. With the veterinary surgeon the disease is seen most commonly in cattle, although one meets with it in the horse, sheep, pig, and even the dog, the latter animal being rather more refractory than the others.

The returns of the chief veterinary officer of the Ministry of Agriculture for 1919 show that Wales had been absolutely free for three years, but that 180 outbreaks were confirmed in England and 59 in Scotland. In all, 275 cattle, 8 horses, 1 sheep, 38 pigs, 1 dog, and 7 ferrets were affected. Twenty-five per cent. of the outbreaks occurred on premises where anthrax had occurred the previous year. The annual average, owing to precautions taken by the officials of the Ministry, has been reduced from about 1000 between 1907 and 1910 to 239 in 1919. The disease is troublesome and difficult to control, but the measures at present taken appear to be keeping it in check.

If only the disinfection of imported things such as hides, wool, hair, &c., can be thoroughly controlled we shall hear of fewer cases in man; the same may be said of the supply of cotton and other cakes imported into Great Britain as a food for cattle. The following were the surmises made as to the source of the 1919 outbreak. (1) Effluent of tanneries or other similar industries getting into streams; (2) feeding of infected offal to pigs; (3) use of imported foodstuffs and artificial manures; (4) contaminated sewage; (5) contact with infected material of other outbreaks.

It is thus by attention to complete disinfection of animal products and sources of contamination by animal products that we shall diminish the chances of human infection. For animals themselves it is a more difficult problem, as so much of their food material must of necessity come from abroad, a good deal of it from countries in which anthrax exists to a considerable extent. The destruction of the spores is the chief difficulty, but a good fight is being maintained, and if only the disease can be kept under control among farm animals the veterinary profession will be doing a good deal towards helping to make it a rare disease in man.

Rabies.

Rabies has had no place in this country for nearly 20 years until lately; the present inconvenience from which dog owners in several parts of England have to suffer is entirely due to the surreptitious importation of some dog in the incubation stage of the disease. All continental countries, with the exception of Norway, Sweden, and Denmark, are infected; although mainly seen in the dog, rabies is also met with in horses, cows, sheep, cats, foxes, wolves, and even fowls, in some of which it produces a train of rather curious symptoms, which to the layman may not give any suspicion of the disease, and thus disaster may be led up to.

Everyone knows something about the suspicious signs in the dog, although the classical symptoms are by no means constant. The change of manner, the desire to hide in dark corners, great excitability towards strange people and strange dogs, restlessness and weariness, snapping at imaginary flies, the attempts to chew and futile attempts to swallow all objects near at hand, the inability to swallow water, the continual salivation, and final violent rage in the mad form—or the typically dropped jaw in the paralytic form—are all characteristic of the rabid dog. It is strange, too, what long distances they will cover in their unconscious frenzy, wandering aimlessly on for miles; and it is for this reason that sometimes a large area or district has to be placed under the restrictions of the Ministry of Agriculture. The voice, too, becomes altered, the bark being hoarse and accompanied by a most peculiar howl, the sound of which when once heard is never forgotten. Paralysis of the hind-quarters and complete exhaustion and coma finally supervene if the disease is allowed to run its course.

In the cat the symptoms are even more violent than in the dog and a rabid cat is even more to be feared by man than a dog. It will bite and scratch, attacking men and animals in a most reckless fashion. The voice changes in tone and, as with the dog, paralysis of the hind-quarters eventually follows. In the horse and ox there is violent excitement; a particular symptom which has been noted again and again is an attempt to bite or rub the scar of the original site of infection, as it is practically always from the bite of a rabid animal that their infection occurs. Sexual excitement is often present. Paralysis of the hind-quarters is the common sequel in all instances, and the disease is always fatal.

The 1919 annual report of the Chief Veterinary Officer of the Ministry of Agriculture showed that 143 cases of rabies were confirmed in that year, there being 140 dogs, 2 horses, and 1 pig. The first case was imported into Plymouth somewhere about May, 1918, and it is to this piece of criminal thoughtlessness on the part of someone that we owe the fact that we are now again an infected country. During 1919 alone some 179 persons were bitten by animals in the scheduled areas, 46 of whom were bitten by animals proved to be rabid. Treatment was arranged by the medical officer of the Ministry of Health, and it is a triumph to the memory of Pasteur that there have been no deaths from hydrophobia.

By the present arrangements the neck and head of any dog which has died or been killed as a rabies suspect is dispatched at once to the veterinary laboratory of the Ministry of Agriculture, together with a history from the field veterinary inspector who made the post mortem. This is then dealt with at once; the Negri bodies are searched for, and if necessary inoculation experiments are made. The result has worked out that in 96 per cent. of cases a decision could be given at once, thus saving those patients who had been bitten much suspense and anxiety; and, what is more, enabling the medical officer to advise and urge immediate anti-rabies treatment.

At the present time the necessity for the muzzling order still exists in certain areas, and both medical and veterinary practitioners must be on the look out for rabies; but there is no doubt that what has been done before can be done again; an island like ours can be rendered free from rabies.

Foot-and-Mouth Disease.

Foot-and-mouth disease, as a disease communicable from animals to man, does not bear quite the same importance as the diseases previously alluded to, but it is important, because, if neglected, it would cause a certain amount of trouble through ingestion of milk. Such trouble is not at all uncommon in countries where foot-and-mouth disease is indigenous; at the present moment in England I am given to understand that there now exists at least one definite case of contagion in an official who was constantly examining mouths and feet. Foot-and-mouth infection can only come from infected cattle, and the disease can also be transmitted not only to man but to the sheep, goat, and pig, whilst horses and fowls are not immune.

In most European countries it always exists, and it is owing to our insular position and to precautions taken by the Ministry of Agriculture that this country was entirely free from 1895 to 1899, and again from 1903 to 1908, with the exception of two small outbreaks which were easily suppressed. The present outbreak is very obscure in origin, and as the virus is invisible and the disease one of the most insidious and contagious in existence, it has presented many difficulties. Had it not been taken firmly in hand at once it would certainly have cost agriculturists millions of pounds, and it is highly probable that another disease would have been added to the medical practitioner's list. As an indication to what extent it will spread it is only necessary to mention that in 1892 in Germany no less than 1,501,299 cattle, 2,193,157 sheep, 17,782 goats, and 438,262 pigs were affected, whilst in other continental countries it raged with equal violence.

Even so recently as the spring of 1919 the North of Italy was visited by a very virulent form, and a great many of the agriculturists of the provinces of Milan, Turin, Tuscany, and Cremona were ruined in consequence, as it affected not only milking cattle but also working bullocks.

Mange.

With regard to mange, the parasite of the disease is in all animals; it is always a source of danger to man, and infection has been noted on many occasions. Three varieties of parasite are found on the horse—a sarcopt, a psoropt, and a symbiot, but it is the two former which give trouble, and man is infected by contact with mangy horses, grooming tools, food utensils, &c., usually on the chest (especially if hairy), the under surface of the forearm, and the hands. Riding a mangy horse has been known to infect men down the inside of the legs and in the public region, and during the recent war this form frequently occurred. Knackermen are often infected when employed in skinning mangy horses. Sarcoptic mange is very troublesome to get rid of in the horse, requiring several months, but the psoroptic variety is much more amenable to treatment.

Sulphur in some form or other is the basis of most treatments. In Great Britain it is a notifiable disease.

That mange in the dog and cat is transmissible to man does not seem so generally known and appreciated as it ought to be, and some time ago Dr. A. Whitfield and I published the histories of 17 cases in which he confirmed the existence of the sarcoptic parasite in the human subject, and I confirmed it in the dog. The owner of a mangy small dog is often found to complain of an irritable skin, usually the region of the inside of the forearm, where the dog rests its head when being nursed. The contact of the warm flesh causes the mange parasite to leave its original host and transmit itself to the human flesh, where it sets up considerable irritation. In some of these 17 instances infection had taken place in the region of the neck and chest, and in one on the abdomen, as a result of the objectionable habit of allowing the little dog to sleep in that situation. The lesions produced were described by Dr. Whitfield as small vesicles, slightly smaller than the ordinary eczema vesicle and surrounded by a narrow zone of hyperæmia, very like that of varicella, only about one-eighth of the size. These lesions were scattered discretely over the surface and not in grouped lesions. The intense irritation leads to decapitation of the little vesicles, and their original site becomes covered with either a serous or a blood scab. If left untreated the parasite will live in the human subject for about six weeks, but if treated, I am told that it is readily got rid of.

In the dog we have two varieties of parasite, the *Sarcoptis conis* and the *Donodax folliculorum*; the latter gives the veterinarian endless trouble, and both are infectious to man. Sarcoptic mange yields readily to treatment, but it takes about a month or six weeks to effect a certain cure. If neglected the dog becomes covered with scabs and sores, gets thin and emaciated, has a peculiar mousy odour, and will eventually die.

I have with me to-night a cat, the subject of sarcoptic mange, really so loathsome and miserable an object that one cannot understand the owner or her servants not having observed its condition long before. This animal has been infected for some weeks and has been wandering about the house without restriction. The uncastrated male cat is, in all large towns, a fruitful source of the spread of sarcoptic mange amongst the females, and, indeed, to other males with whom he is constantly at war.

Ringworm.

Ringworm of the horse, calf, dog, and cat are the ones which interest us most to-night from the point of view of contagion to man. All are contagious and give considerable trouble in their treatment. In country districts the calves are the constant source of infection, in town the cat is mostly the culprit. Dr. Whitfield has recorded several such cases, as have also others.

Measles in Beef and Pork.

Measly beef is, as you know, due to the *Cysticercus bovis*, the larval form of the *Tænia saginata* of man. The *Cysticercus cellulosæ* in the muscle of the pig is the larval form of the *Tænia solium* in man. It is to be remarked that the general neglect of proper meat inspection in England is lamentable. Fortunately we cook our food well, and to this custom we owe a good deal of freedom from disease.

Trichinosis.

Trichinosis is a parasitic affection in the muscles of the pig, from which it is transmitted to man in sausages or other infected food which has not been thoroughly cooked. Dogs and rats, amongst other animals, are also subjects of this disease; the pig is infected by eating rats and mice and the flesh and offal of other infected pigs. The disease is met with in Germany, America, and other countries, special systems of meat inspection being necessary on account of its prevalence.

Tuberculosis.

The subject of tuberculosis had, perhaps, better be left to be introduced and discussed on another occasion. It is contagious from animals to man, and the questions of clean milk and clean meat are too important for casual treatment. Before the war the matter of a clean milk-supply and the eradication of tuberculosis from our herds of cattle was being taken up with vigour, and it is soon to be taken up again. It is very necessary to root this disease out from our herds in order to assist in its disappearance from man. I merely mention it, for the subject has so many sides to it that I feel we could not half do it justice.

Conclusion.

In conclusion, I wish again *to draw attention to the part* played by animals in transmission of certain diseases to man, and to emphasise the extent of ground common to workers in human and veterinary medical science. By joint action much valuable time may be saved and much better results obtained than by holding aloof in separate compartments.

TAPEWORM HOSPITALITY.

To the Editor of THE LANCET.

SIR,—A patient in Khartoum Civil Hospital, treated once in the ordinary way with filix mas, has produced 31 specimens of *Tænia saginata*. Is this a record?

I am, Sir, yours faithfully,
V. S. HODSON,
Director, Khartoum and Omdurman Civil General Hospitals.
March 10th, 1921.

PRACTICE BY FOREIGNERS IN CHILI.

FOREIGNERS in Chili are becoming aware of the turn of the screw against internal competition by non-Chilians in various trades and professions. For some years the law has forbidden medical practice to any who do not hold the State diploma, but until lately the interpretation of this law was not strict. The attention of the local medical society was directed by a practitioner to the position of the resident medical officer of the English hospital, with the result that his and all medical diplomas were carefully scrutinised. The three assistants at the German hospital are in similar case and a German dentist has already been obliged to leave Valparaiso.

LEARNED SOCIETIES.

THE thirty-seventh annual issue of the Year Book of the Learned Societies of Great Britain and Ireland (London: C. Griffin and Co., Ltd. Pp. 354. 15s.) is compiled from official sources and purports to be a record of work done in science, literature, and art during the session 1919-20. The claim is a large one and its full execution beyond human endeavour, while we gladly acknowledge to finding the year book a valuable book of reference, giving, as it does, not only the addresses, names of officials, dates of meeting, and other useful information, but also lists of the papers read at the different societies. A comparison of the current issue with its predecessor shows that, while a few societies have ceased operation, others have come into being, and necessitated an addition of nearly 20 pages to the book. Medicine, which in 1919 occupied 35 pages, now occupies 41, and biology, including microscopy and anthropology, which formerly had 44 pages devoted to it, now has 47. Psychology remains as previously with 7 pages, and general science with 53 pages. The field of medicine is not quite evenly covered, for while the programme of St. Mary's Hospital Medical Society, which includes papers by Sir Almroth Wright and others, is given, there is no mention of other students' societies of older foundation, such as the Abernethian Society of St. Bartholomew's, the Hunterian Society of St. George's, or the Physical Society of Guy's.

THE REMOVAL OF TATTOO MARKS.

As a result of the social upheavals of the war many persons have emerged from strata of society where tattooing is regarded as highly artistic to find themselves in strata where it is looked upon as vulgar and the badge of a savage. Little wonder, therefore, that a fresh impulse has been given to the art—a highly complicated and difficult art—of removing tattoo marks without further disfiguring the skin. Even in the time of the Roman Empire many devices were employed towards this end, and a paper by Dr. P. Cattani of Zurich (*Schweizerische Medizinische Wochenschrift*, Feb. 10th) shows that as many as 13 totally different methods have been devised, none of which can be said to be at once painless, easy, and effective. His detailed description of each method reveals an extraordinary degree of ingenuity on the part of cosmetic specialists, and, in some cases, marvellous powers of endurance on the part of their patrons. Dr. Cattani himself has practised only a few of these methods, *and the four which he finds the most successful* are Variot's, galvano-cauterisation under local anæsthesia, "harpooning" or digging out each granule of pigment (Wederhake's method), and excision of the skin. Variot's procedure begins with a preliminary cleansing of the skin, on which a concentrated aqueous solution of tannin is applied. With the tattoo needle the pigmented area is now freely punctured, and into the punctures thus made silver nitrate is repeatedly rubbed, and the skin is then strewed with powdered tannin. A protective dressing is applied, and after a short time a violent inflammatory reaction follows, with swelling and necrosis of the skin. After two to four weeks the crust thus formed is discharged, and the underlying structures, which are at first red, pale gradually in a few months. A slightly raised scar is left to indicate the original site of the tattooing. Dr. Cattani has never seen permanent ill-effects follow this method which, he admits, is painful as well as requiring much time and patience. He refers to a fatal case recorded by Parent-Duchatelet in 1857. The patient was a prostitute, whose reaction to the removal of tattoo marks by caustics terminated in death. To judge by Dr. Cattani's accounts of this and other methods of removing tattoo marks, it is abundantly evident that prevention is better than cure.

An Address
ON

THE COLONIAL MEDICAL SERVICE AS A CAREER.*

By Sir JAMES K. FOWLER, K.C.V.O., C.M.G., M.D.,
CONSULTING PHYSICIAN, MIDDLESEX HOSPITAL, ETC.

GENTLEMEN,—I have been asked to address you by some members of our profession who are deeply interested in the medical and sanitary problems with which the Colonial Medical Service has to deal, and who, having had personal experience of the work of the Service in various parts of the world, desire that it should become better known.

Since the year 1908, when I was invited to be a member of a Departmental Committee which was then appointed by the Secretary of State to consider certain questions that had arisen in regard to the West African Medical Staff, I have been sincerely interested in all that concerns the welfare of the personnel of that and other units of the Colonial Medical Service. As chairman of the subcommittee on colonial medical appointments, which interviews and classifies the candidates, I have had for the last 12 years the pleasure of meeting all who have entered the service since that date; and as chairman of the Yellow Fever Commission I formed the highest opinion of the work of the many distinguished members of the West African Medical Staff who were appointed to investigate on the spot the problems with which that Commission had to deal. As a member of the Departmental Committee on the Colonial Medical Services, whose report was issued in August of last year, I was, moreover, able to learn what is in the minds of all those who are interested in those services.

STATIONS OF THE COLONIAL MEDICAL SERVICE.

The Dominions overseas of the British Empire differ, as you are aware, in the degree of their dependence upon the mother country, but, as was seen during the war, not in the degree of their attachment to the Crown. With the self-governing Dominions Canada, New Zealand, the Union of South Africa, Newfoundland, and the Commonwealth of Australia we are not to-day concerned, as they select and appoint their own medical officers. In some of the colonies only the senior medical appointments are filled by the Secretary of State usually by transfer from other colonies, the junior officers being natives of the country and appointed by the Governor.

The colonies in which any of you who may enter the Colonial Medical Service are likely to find the best opportunities for the exercise of your abilities and for a career on which you will be able to look back with satisfaction are those in which there is a large staff wholly appointed by the Secretary of State. This applies specially to the West African Medical Staff, the East African Medical Staff, and the Malayan Medical Staff.

The Colonies and Protectorates to which medical officers are appointed by the Secretary of State for the Colonies are:—

(*a*) The West African—viz., Nigeria, the Gold Coast, Sierra Leone, and the Gambia.

(*b*) The East African—viz., the Kenya Colony and Protectorate, the Uganda, Nyasaland, Somaliland, and Zanzibar Protectorates and the Tanganyika Territory.

(*c*) The Eastern—viz., Ceylon, the Straits Settlements and Federated Malay States, Hong-Kong, Weihaiwei, Mauritius, and the Seychelles.

(*d*) The West Indian—viz., British Guiana, Jamaica, Trinidad, Tobago, the Windward Islands, the Leeward Islands, Barbados, British Honduras, and the Bahamas.

(*e*) Fiji and the Western Pacific, Cyprus, Malta, Gibraltar, St. Helena, Bermuda, and the Falkland Islands.

In Ceylon, Mauritius, Jamaica, Barbados, the Bahamas, and Bermuda vacancies in the junior ranks are practically always filled locally by the appointment of qualified native candidates; in the case of some of the higher posts—by transfer from other colonies. Appointments in Malta are all filled locally. Vacancies in the Hong-Kong Medical Department have in the past generally been filled by transfer from other colonies. The total number of appointments filled by the Secretary of State is about 620.

Vacancies occur most regularly and frequently in (1) the West African Medical Staff; (2) East Africa; (3) the Straits Settlements and Federated Malay States. In nearly all cases the vacancies for which medical officers are selected by the Secretary of State are in the junior grades of the service. The senior appointments, especially those in the more healthy colonies, are almost invariably filled by the promotion of officers who have rendered good service in the same or in other colonies.

Let us now in imagination start on a voyage round the world. We arrive first at Gibraltar, which no Englishman can see for the first time without a thrill. Here are three surgical appointments attached to the Colonial Hospital. These are very desirable appointments, two of which have recently been filled by men with high surgical qualifications. In Cyprus there is a chief medical officer and five district medical officers.

THE WEST AFRICAN MEDICAL STAFF.

Returning and proceeding down the coast of Africa we pass in succession the colonies in which the West African Medical Staff are employed—viz., the Gambia, Sierra Leone, the Gold Coast, including Ashanti and the Northern Territories, and Northern and Southern Nigeria, now united as Nigeria.

The West African Medical Staff is the most highly organised and possibly the most efficient unit of the Colonial Medical Service. It stands to the West African Frontier Force in the same relation as the R.A.M.C. does to the Army. Its members have taken part in all the various wars in Africa, and during the late war they rendered distinguished service in the campaign in the Cameroons and East Africa, for which latter campaign some of them were lent. Officers are liable for service in any one of these colonies, but an attempt is always made to meet the wishes of an officer for a particular colony on first appointment.

As you are doubtless aware, the West Coast of Africa has had in the past an evil reputation from a health and climatic point of view. There is now a tendency in some high quarters (not in this country) to suggest that it has become almost a health resort. That such a claim or any approach to it should be made is the highest possible tribute to the devoted labours of the West African Medical Staff and to the medical departments of the Governments of those colonies by whom their work has been directed. I am far from suggesting that this era began with the appointment of Mr. Joseph Chamberlain as Secretary of State for the Colonies, but his name should always be mentioned with honour whenever the success which has attended the efforts of the Colonial Medical Service to promote the welfare of the European and native inhabitants of our colonies is brought to mind. It was Mr. Chamberlain who first established at the Colonial Office the traditions and high ideals in regard to tropical sanitation, which his successors there have worthily maintained. The contention now is, briefly, that in West Africa there is very little wrong with the climate, it is the diseases that matter, and that we now know how to prevent and treat those diseases, the most important and most prevalent of which is, of course, malaria. I cannot go quite as far as some are prepared to travel in this direction, but to discuss the question at length is beyond the scope of my address. That one is constantly meeting men who have been on the coast for years and who have not apparently suffered in health is a fact that cannot be ignored. I believe that it is largely a personal matter, firstly of natural resisting power and secondly of a rigid adherence to the laws of health which residence in tropical countries requires from Europeans if they are to escape the maladies incidental to life in those parts of the world.

---

* This address to students was delivered at the Middlesex Hospital, and subsequently at Guy's Hospital.

Since this address was first delivered the vital statistics for West Africa from 1903 to 1919 have been published in an official paper. The facts as regards the death-rate for non-native officials are, very briefly, as follows: The highest death-rate during that period was in 1905 = 28·1 per 1000. Subsequently, with the exception of a slight rise in 1910, there was an almost continuous fall until 1916, when it was *10·3* per 1000. There has since been a slight rise owing to the influenza epidemic, but the rate is now again falling, and in 1919 was *12·5* per 1000. In this statement the losses during and owing to the war are not included. I may remind you that the death-rate for the United Kingdom in 1918 was 17·6 per 1000, but I must hasten to add that these figures are not really comparable, as the non-native officials in West Africa have been subjected to a medical examination.[1]

I have examined the returns giving the cause of death amongst the members of the West African Medical Staff which have occurred since the year 1908, when I first began to have a knowledge of their existence as a body. From these it appears that in the 13 years under review, climatic conditions are mentioned in the certificates of death in 7 cases only. In 4 cases malaria in some form is mentioned primarily; in 1 case dysentery is given as a secondary cause; in 1 case enteric fever is given as the primary cause, and in 1 influenza. The authorised establishment of the West African Medical Staff is about 250.

The most attractive and the most healthy regions in the West African colonies are on the high lands in the neighbourhood of Kano in Northern Nigeria, where there is a large Arab population, nearly all of whom are Mahomedans. Togoland was the first of the German colonies to be taken. A small detachment "on their own" paid a week-end visit to Lomé, the capital, and annexed the country. About one-third of Togoland has been added to the Gold Coast Colony, the remaining two-thirds to the French colony of Dahomey. As a result of the war about one-tenth of the area of the German colony of the Cameroons has been added to Nigeria in the form of a narrow strip along its eastern boundary which contains Buea, a mountain station that may be of use as a health resort, but during some months of the year mist is very prevalent there. The remainder of the colony has become French territory.

THE EAST AFRICAN MEDICAL STAFF.

Rounding the Cape of Good Hope and going northwards we pass Mauritius. In the Seychelles Islands, much further to the north, there are three appointments. We now come to the East African colonies—Nyasaland, Kenya (late British East Africa), Uganda, Tanganyika Territory (late German East Africa), and Zanzibar. The medical staffs of these various colonies are now in process of amalgamation into a single medical unit to be called the East African Medical Staff, and in future officers will be liable for service in any one of the colonies of the group as in West Africa. The authorised establishment of the East African units prior to amalgamation was 139. There are now many vacancies owing to the general shortage of medical men available for civil and Government employment, the result of the war and the absence of recruiting for the service during the war. Mombasa is the largest town and the principal port of Kenya Territory, and is also the starting-place of the Uganda railway, which runs through Nairobi, the capital of the Protectorate, to Kisumu, Port Florence on the Victoria Nyanza, a distance of 584 miles. Those who have read "The Man Eaters of Tsavo," by Colonel Patterson, should they ever pass that station, 133 miles from Mombasa, will call to mind the thrilling incidents of that story. Nairobi, 327 miles from Mombasa, is situated on the highlands or central plateau at an altitude of 5450 feet above the sea-level. The great game preserves are on either side of the railway before Nairobi is reached. The highlands have a temperate climate; the mean average temperature at noon is 78° F. July, August, and September are usually cold months. There are many European residents on the highland plateau, and their number is constantly increasing. Those who are interested in the East African colonies may be confidently recommended to read "Uganda for a Holiday," by Sir Frederick Treves, who combines with the highest distinction in surgery a love of travel and a literary style which make the descriptions of his journeys fascinating guide-books for those who follow in his footsteps. My colleagues at the Middlesex Hospital, Sir John Bland-Sutton, in "Man and Beast in Eastern Ethiopia," and Dr. Comyns Berkeley in "On Safari," have also given interesting accounts of a visit to these colonies. Somaliland is not to be included in the East African unit, and from the despatches I have read I do not gather that it is a very desirable station, although it was lately the scene of one of the cheapest and most successful campaigns for which the Colonial Office has ever been responsible, and the first in which aircraft played an absolutely dominating rôle.

THE MALAYAN MEDICAL STAFF.

Crossing the Indian Ocean we arrive at Ceylon. Here only the higher posts in the medical department are filled from home; the other officers fo the most part hold the licence of the Ceylon Medic College, which is recognised by the General Medic Council as a registrable Colonial qualification. Fr Ceylon we cross to the Straits Settlements, Pena Malacca, and Singapore, and the Federated and U federated States of the Malay Peninsula, where the a large medical service, which the departmental c mittee of 1920 have recommended should b the Malayan Medical Service. This is ent from home. The authorised establishm unification was 82 medical officers.

CHINA AND THE WESTERN PAC

In China there are medical appointments a Kong and at Weihaiwei, where there are two m officers. In Fiji there are at present 18 medical officer three of whom are also magistrates, in addition to a chief medical officer, a medical officer of health, and a senior medical officer. The medical services of Fiji and the Western Pacific are interchangeable; officers may be transferred from one to the other at the discretion of the Secretary of State. The staff in the British Solomon Islands Protectorate consists of one senior and two junior officers. In the Gilbert and Ellice Islands there is one medical officer in charge.

THE WEST INDIAN GROUP.

Rounding Cape Horn we come to the Falkland Islands, where there are two appointments. The first British colony as we go north along the coast of South America is British Guiana, where there are 33 appointments, including a surgeon-general. In Trinidad and Tobago there are approximately 40 medical officers. In the Windward Islands, Grenada, St. Lucia, and St. Vincent there are 25 appointments, with the right of private practice. Officers may be transferred from one island to another at the discretion of the Governor. In the Leeward Islands, Antigua, St. Christopher and Nevis, Dominica, Montserrat, and the Virgin Islands there are 24 appointments. British Honduras is a colony on the east coast of Central America. The medical staff consists of a principal medical officer, who is allowed to undertake consulting practice, and five assistant medical officers. Bermuda or the Bermudas, for the colony really consists of the main island and a group of about 300 smaller islands, is on the Western Atlantic, and has a small medical service. This completes our tour of the colonies.

PAY.

The attractions of any Government service in these days depends very largely upon the salaries which are offered and on the prospects of promotion and pension and a career. Probably the majority of salaried officers of any public service of any country are of opinion at the present time that their pay is inadequate, and many of them have good grounds for so thinking. The Departmental Committee (1920) learned from the witnesses that the increase in the cost of living is universal; there is not even a "bush station" in West Africa where the effect of the war in increasing the cost of the necessaries of life has not been felt, although the effect is greater in towns on the coast than in the interior.

---

[1] The death-rate for London for the week ended Feb. 26th, 1921, was 15·1 per 1000, and for 96 English and Welsh towns 15·5 per 1000.

The salaries attached to the medical appointments in the various colonies are not uniform, and in some few cases are to be regarded more as retaining fees for the performance of certain Government duties than as adequate for whole-time employment. This does not, however, apply to those units in which the rates of pay are fixed by the Secretary of State, such as the West African Medical Staff and the East African Medical Staff, and it will, I think, give you a better idea of the prospects which await you in the service if I state in some detail the salaries which are now offered in those two units.

Pay in the W.A.M.S.

A considerable addition has lately been made to the rates which were in force before the war in regard to the West and East African appointments.

On appointment as an officer of the West African dical Staff on probation the initial salary is at the e of £660 a year, rising by annual additions of £30 to a year. After three years on probation, if then rmed in the appointment, the salary rises by I al additions of £40 to £960, with proficiency pay at a ate of £72 a year. Before, however, passing £800 a cal officers are required to take a special course of th for three months. If they obtain satisfactory gui ates at the end of the course they draw their who increments up to £960 a year. These are certifi- prob satisfactory attendance, not necessarily of As passed an examination.

Colo regulations in regard to the special course of Au are as follows:—

approved course of study is the three months' course he West London Post-Graduate College or the London ool of Clinical Medicine, Greenwich, in clinical medicine, nical surgery, and pathology.

fficers are allowed to substitute for this course either the course of study and examination for a recognised loma or degree in public health, sanitary science, or State edicine; or (ii.) the course of study and examination for a rther medical or surgical diploma or degree; or (iii.) if the overnor, on the recommendation of the principal medical officer, approves, a course of study in some special branch of medical or surgical practice—e.g., ophthalmology, dermatology, genito-urinary diseases—or an advanced course at the London or Liverpool School of Tropical Medicine.

Whichever of these courses of study is selected, the necessary tuition and examination fees are paid by the Colonial Government, except in the event of an officer deciding to enter for a further medical or surgical diploma or degree, in which case no fees are paid.

A medical officer who has served for three years on the maximum salary of this scale (£960) without obtaining promotion is eligible, if recommended by the Governor, to be placed on the scale of £1000, with annual additions of £50 to £1150, with £100 proficiency pay. This is the same rate of pay as that of senior medical officers.

There are seven appointments of sanitary officer, with salary at the rate of £1050 a year, rising by annual increments of £50 to £1200 a year, and a duty allowance at the rate of £210 a year.

The first step in promotion is to that of senior medical officer, in which grade there are 20 appointments with salary, as just stated, at the rate of £1000 a year, rising by annual increments of £50 to £1150 a year, and proficiency pay at the rate of £100 a year.

There are also seven appointments bearing the title of provincial medical officer—two each in the Southern Provinces, Nigeria, in the Northern Provinces, Nigeria, and in the Gold Coast respectively, and one in Sierra Leone, with salary at the rate of £1200 a year, and duty allowance at the rate of £240 a year.

There are four appointments of the grade of senior sanitary officer, one each for the Northern Provinces, Nigeria, the Southern Provinces, Nigeria, the Gold Coast, and Sierra Leone. Salary at the rate of £1300 a year is attached to these appointments, together with a duty allowance at the rate of £260 a year.

The next higher rank is that of deputy principal medical officer, in which there four appointments, two in the Southern Provinces, Nigeria, and one each in the Northern Provinces, Nigeria, and the Gold Coast respectively. Salary at the rate of £1300 a year, is attached, together with a duty allowance at the rate of £260 a year.

Principal medical officers receive salaries as follows:—In the Gold Coast and Nigeria, £1500 a year, with a duty allowance at the rate £300 a year. In Sierra Leone, £1350 a year, with a duty allowance at the rate of £270 a year. There is no principal medical officer in the Gambia. The director of the medical and sanitary service, Nigeria, receives a salary of £1700 a year, with a duty allowance at the rate £360 a year.

There are in addition various special appointments—e.g., (*a*) the director of the Medical Research Institute, Lagos, and the pathologist, Accra, receive a salary of £1300 a year, with a duty allowance of £260 a year. (*b*) Salary at the rate of £800 a year, rising by annual increments of £40 to £960 a year, is attached to about 10 posts (those of assistant at the Medical Research Institute, Lagos, and medical officers of health at various places). In addition to the proficiency pay (£72 a year), staff pay at the rate of £150 a year is also attached to these posts; and the holder of the appointment draws half of the staff pay during leave of absence, the remainder being drawn by his locum tenens. The holders of these appointments are not allowed private practice. Duty allowances, proficiency pay, and staff pay are not pensionable emoluments.

Private Practice.

All officers of the W.A.M.S., except principal and deputy principal medical officers, provincial medical officers, sanitary officers, and a few other officers holding special appointments, are allowed to take private practice, provided that it does not interfere with the faithful and efficient performance of their official duties, but it is within the power of the Governor to withdraw or to suspend the privilege in such places and for such periods as he may consider desirable.

The Colonial Office is always very careful to make it clear that private practice does not exist at the majority of stations, and no guarantee is given that an officer will be posted to a station in which he will be able to practise privately. As a general rule, stations where there is private practice are allocated to senior members of the staff. In West Africa, as elsewhere throughout the world, success in private practice depends very much on personality.

Gratuity.

An officer of the West African Medical Staff may, at the end of nine years (of which not less than six must have been residential) retire with a gratuity of £1000, or at the end of 12 years (of which not less that eight must have been residential) with a gratuity of £1250. In the event of an officer dying in the service after completing the period of residence qualifying him for the smaller or the larger of these gratuities, a sum equal to the gratuity in question is paid to the credit of his estate.

Quarters.

At all the recognised stations single quarters, free of rent (but not of rates and similar outgoings), are provided for medical officers, or an allowance is paid in lieu of quarters.

Pensions.

I shall only give a brief, and necessarily incomplete account of the regulations relating to pensions and gratuities for the West African Service. Moreover, alterations in the West African regulations as to pensions are under consideration. On attaining the age of 50 years, or after 18 years' service (of which at least 12 must have been residential), an officer is qualified for a pension. If invalided after a minimum of seven years' service he still is qualified for a pension. If invalided before completing seven years' service he is qualified for a gratuity not exceeding three-quarters of a month's salary for each six months of service, provided that he has been confirmed in his appointment.

The method of calculating the amount of a pension appears at first sight somewhat complicated, but it is really simple. To the maximum salary of which the officer has been continuously in receipt an addition of from £40 to £80 is made to represent the value of free quarters. The sum so obtained is then divided by 40, which, it may be mentioned, is a more generous figure than in the Home Civil Service, in which the division is into sixtieths. This figure is then multiplied by the number of years he has served, and the result is the amount of his pension. As an example, an officer who has served 18 years satisfactorily, even if he has never been promoted from the lowest rank, obtains a pension of £553 10*s.* per annum.

A book is issued by the Colonial Office called the "West African Pocket Book," which contains much more detailed information than I have here given on the various matters mentioned.

Pay in the East African Colonies.

The salary on first appointment of a medical officer in any one of the East African colonies is now (1920) £500 per which admission is obtained by competitive examination stands on a higher level of regard than one which is entered by selection. I ventured to propose, and the Departmental Committee accepted the suggestion, that there should be a single entrance examination for all the public medical services. I believe that such a change would be to the advantage not only of the Services concerned, but also to that of the students in the schools. The suggestion received the support of your Dean (Middlesex Hospital), who brought it before the Committee of Deans of the London Medical Schools, by whom it has been adopted and forwarded to the heads of all the Government departments concerned.

Here, again, the Committee have been anticipated by Sir George Evatt. Under the heading "Entrance to the Service to be by Public Competition," he writes as follows:—

> "I think the day for nomination in the public services is now over. Appointment by nomination without competition is still the rule in the Colonial Medical Service. ...... The Secretary of State for the Colonies would each year notify the vacancies likely, and the competition would be on the same lines as that for the Army Medical Services. This would require the conditions of service to be placed before the medical public, and young medical men would decide into which service they would propose to enter. Pension rules, pay, honours, and rewards would thus become known to all."

There is in this suggestion nothing either novel or revolutionary, as it is the method adopted by the Civil Service Commissioners in the examination for admission to the public services. If this proposal should come into force it would, I think, be necessary that there should be a preliminary interview with a joint committee representing the various departments, and that the candidate should be approved for the service or services for which he had entered his name. To take the case of the Colonial Office as an example, it could not be expected to regard the possession of a qualification to practise as constituting by itself a sufficient proof of fitness for the responsible duties attaching to an appointment in the Colonial Service.

There is much inflammable material in Africa and elsewhere, and the possession of tact and judgment is necessary in those called upon to deal with native races if it is to be prevented from taking fire.

SECONDING FOR RESIDENT APPOINTMENTS.

If the recommendation as to admission by an examination test is adopted it carries with it an important proviso—viz., that the men selected may be seconded for a resident appointment, such as house surgeon or house physician, preferably at the general hospital where they have obtained their education in the practical subjects of their profession, or, failing that, at some other general hospital possibly not attached to a medical school, but approved for the purpose by the Secretary of State. This system of seconding recently appointed officers has been adopted by the army and has proved successful. The individual gains experience and his services become more valuable to the State.

I have a profound belief in the importance of holding resident appointments at that receptive period of one's life, preferably under one's own teachers. Indeed, when I was myself at that stage we were so insufferably conceited as to think that a man was then at his best, and that he steadily deteriorated from that time onwards. At the termination of their appointment officers who have been seconded and all others not so seconded would, as at present, be required to attend a course at the School of Tropical Medicine either in London or Liverpool of two or three months' duration.

THE FUTURE OF THE SERVICE.

All who are interested in the future welfare of the Colonial Medical Service will be in accord with the hope expressed in the concluding paragraph of the Report of the Departmental Committee of 1920:—

> "The Committee believe that by the adoption of the above measures ...... the Colonial Medical Service will attain to a very high, possibly even to the highest, status amongst the public medical services of the Empire."

If anything I have said should lead any of you to select the Colonial Medical Service, I trust that you will never have reason to regret your choice.

A Clinical Lecture

ON

WHEN TO OPEN THE MASTOID ANTRUM IN ACUTE EAR DISEASE.

Delivered at Guy's Hospital on Feb. 28th, 1921,

BY T. B. LAYTON, D.S.O., M.S.LOND., F.R.C.S.ENG.,
SURGEON TO THE THROAT AND EAR DEPARTMENT.

> "I beseech you, think it possible you may be mistaken."
> —*Oliver Cromwell.*

IN surgery there are three things to learn: how to operate, when to operate, and when to stop. The first is easy and can be learnt in time by anyone with industry who will trouble to watch other people do it first. The second is hard; it is learnt only by experience guided by rigid self-criticism as well in success as in failure. The third is so difficult that it is only one or two in a surgical generation who attain to it. It is of the second of these two that I wish to speak to you to-day in relation to acute ear disease.

Now the mastoid has been called the appendix of the ear, and in many ways the resemblance of acute ear disease to appendicitis is close. Some of you may remember a series of six clinical lectures on appendicitis given by our senior surgeon, and how he finished them by saying, "and remember, you fellows, it is damnably misleading." In that way acute ear disease resembles appendicitis, *for there is no condition which needs* such careful examination, consideration, and judgment as this, and in which you may even then find yourself so entirely in the wrong. It resembles acute appendicitis also in this, that once you have made up your mind that an operation is necessary you should operate that day and not defer it to the next. I remember an occasion on which a house surgeon to Sir Arbuthnot Lane was taken ill, and Mr. Lane, as he then was, felt undecided as to whether it was appendicitis, and, if so, whether it were not better that he be treated medically. He asked Sir William Hale-White to see him, and the latter went round to Mr. Lane's house after dinner and told him he thought it was a case of appendicitis and that the appendix should come out next day. But once the decision was made Mr. Lane did not wait; he put Dr. Hale-White, Mr. Fagge, and Mr. George Rowell into his car, and together they descended on to the hospital at about 9 o'clock in the evening. I would urge that whenever possible the same rapidity of action should follow the decision in cases of acute ear disease. There are some, I believe, who now teach that an operation should be done whenever an appendicitis is diagnosed. If you are of this school, then I would say that in this appendicitis differs from acute ear disease, for there are stages of the latter which are better left alone and for which operation should not be done, and the reason why acute ear disease differs from appendicitis in this point is that in the latter it is possible entirely to eradicate the offending part; in the former it is not. We can compare a simple acute otitis media to that stage of the appendicitis where the mucous coat only is inflamed and where the inflammation has not yet spread to the deeper layers. If we can diagnose this stage exactly we can remove the appendix in safety and without harm to the patient, but we cannot do the same to the middle ear. In the next stage we can compare the spread of the inflammation to the mucous membrane of the mastoid antrum with its extension to the muscular coat of the appendix. From each a recovery is possible, but the inflammation is dangerously near to the third stage, in which the peritoneum is involved on the one hand and the bone on the other. Here, again, could we tell exactly from our symptoms the pathological conditions beneath, we can remove the appendix without infecting the peritoneum, but we can neither remove nor open the mastoid antrum without infecting the osseous tissue of the mastoid.

Further, we have in the ear a minor surgical procedure which may lead to recovery which we have not in this stage of appendicitis. I refer to puncture of the drumhead. There is another way in which appendicitis differs from acute ear disease. It is that if the diagnosis that has been made is wrong in the one case operative treatment may lead you to another lesion which can be dealt with by operation, and in the other it will not. If when the abdomen is opened the appendix is healthy a cholecystitis, a Richter's hernia, or a suppurating tube may be discovered and amended, but if a healthy mastoid be opened there is no neighbouring structure which may have caused the symptoms. Where a diagnosis cannot be made the same principle applies in the two conditions; a person with chronic appendicitis may develop pneumonia or he may get an acute attack in his appendix. If you are confident that it is pneumonia you would not advise that the appendix be removed during the acute illness, but if you could not be sure you would argue that it was safer to open the abdomen during an attack of pneumonia than to leave an appendix which had given rise to such symptoms. So also a child who has long had a running ear may develop acute symptoms which may be due to pneumonia or to the onset of an acute mastoiditis. If you were to find a patch of consolidation which you thought might account for the symptoms you would hold your hand, but if you thought the clinical picture looked like pneumonia but did not feel sure, you would advise an exploration of the mastoid.

THE CLINICAL ASPECT OF THE PROBLEM.

I would have you consider this problem from the clinical aspect, and would have you remember that the word "clinical" infers a double standpoint. There is to be considered the position of the practitioner and of the patient. Working at a large hospital as this, with all the appliances of modern science to our hand and specialists in every branch of medicine to give us help, we are apt not to consider the difficulties that face the man who is working on his own and the alternatives on which he must fall back when he cannot attain to the ideal. My experience has not been great but it has been varied. Before I became surgical registrar to this hospital I spent a wander year. I went to Buenos Aires on a cargo boat carrying emigrants in which I operated on the chart-room table while the steward gave the anæsthetic. I was an assistant to a doctor in a small town up in Yorkshire where the practice extended nine miles out on to the Wolds. I did a locum not far from here and had the experience of being "ticked off" over the telephone by a youthful but unsympathetic house surgeon. I was house surgeon to a small county hospital and medical officer to a large Poor-law infirmary in both of which good surgery was to hand, but there was not the constant readiness to which we are accustomed here, nor the special advice upon allied branches of medicine that is always at hand. Recently I have had a longer period of a still more varied experience. I do not mean that I have had to deal with a case of acute ear disease in every place that I have been, but I have had to deal with some form of acute disease, and I have acquired the habit of considering how I should have dealt with the case before me under such and such circumstances, and above all, I have had experience of how great a responsibility it is to disturb the peace and quiet of some happy home by exploding the bombshell of an urgent and instant operation upon them. I do not mean that I would shirk such responsibility or have you do so, but I would have you realise what it is that you may know what you are doing when you lightly advise some instant operation which subsequently proves not to have been needed. Nor do I mean that I would have you refrain from giving the best of treatments here in order that you may have had experience of the next best; but supposing you have to fall back upon it I think you will be better prepared to face an unusual emergency if you have considered the possibility of its occurrence than if you have never given a previous thought to it. A consideration of cases which have got well under less good circumstances is a healthy stimulus to self-criticism of our successful cases, especially when some action of our own, such as an operative interference, has preceded this success. It is not hard to be self-critical in cases of failure where a little thought may enable us to realise where we have gone wrong, and a natural desire to prevent others doing so will lead us to tell them all about it. It is becoming almost fashionable to publish our tragedies and mistakes: we can almost hear the words of thanks for our courage in bringing forward the case. It is much more difficult to be self-critical in success. Modern psychologists tell us that pleasure is derived from the feeling of having accomplished something, of something attempted, something done; and when we publish our series of so many hundred mastoid or abdominal operations it is hard to turn round upon ourselves and ask in how many of these cases might an equally successful result have been obtained without all the pain and discomfort to the patient and anxiety to his relations that is attendant upon an operation without consideration of the risk. Yet we must ask ourselves this, and an experience of work in other places than the narrow walls of a large hospital will best enable us to do it. It is unfortunate that any one person in general practice sees so few examples of one type of case that he is unable to get enough to put against the lists of successful operations.

THE MENTAL ATTITUDE OF THE PATIENT.

Let us turn then from the practitioner to the patient, and first I would have you consider the mentality of the patient and the importance of studying the same. For, indeed, this is not often studied, and many think that the estimate of the same comes only by experience. I do not deny that in this more than of any other branch of our art experience is valuable, but I would impress upon you that the sooner you begin to study it the sooner will experience help you in the same. The greatest clinical teacher that Guy's has had on the surgical side within my memory has recently said[1]:—

> "The mental attitude of the patient must be studied; he must be considered as a man, as a sensitive being. The special reactions of each individual to his surroundings and to the disease from which he suffers must be noted. The student must learn to set a value on signs, which are not to be estimated by any physical apparatus; in children to interpret the meaning of a cry, a restlessness, a refusal of food."

In no type of case that I know is this study of more importance than in acute ear disease. The ease with which a diagnosis is made is infinitely greater in the stolid quiet child than in the highly strung excitable one. The difficulty of the interpretation of signs in some patient worn out by former anxiety or illness is infinitely greater than in the case of an acute infection in a previously healthy person.

PATHOLOGICAL CONSIDERATIONS.

Before we classify the clinical conditions under which we must discuss the need to open the mastoid let us consider the pathological conditions which may be present. An acute inflammation of the tissues of the middle ear is the start, and this passes over into the mastoid antrum and leads to an inflammation of the mucous membrane of that cavity. This is the earliest stage of an acute mastoiditis, and it is probable that this occurs in the vast majority of acute inflammation of the middle ear. It is not a condition which must need operation, but in its early stage is amenable to other treatment. It is when this passes on to a suppuration of the lining of the cavity, to ulceration of the mucous membrane, and to an acute osteitis of the mastoid process that operation becomes imperative. It is the difficulty in deciding when this has happened that is the problem. If the disease is allowed to go on under your eyes to a further stage you may consider that you have deferred operation too long; and this further stage is the extension of the inflammation from the bone to the surrounding structures. The least harmful of these extensions is to the periosteum. I am going to consider the case with swelling behind the ear no more; it is a question of diagnosis and we are not discussing diagnosis to-day. You may hesitate a bit as to whether such a swelling is due to the middle ear or is in some neighbouring structure, but once you have decided that it is due to the ear you must not hesitate to operate. The next of the structures to which the disease may spread are those within the cranial cavity; if you have evidence of early meningitis you must operate, but it is not good medicine. You must aim at decision before these symptoms arise, and if you save such a case your pride at doing so must always be tempered by the thought that the disease should not have gone so far. And the third structure is the lateral sinus with the jugular bulb.

---

[1] The Hunterian Oration, by Sir Charles J. Symonds, THE LANCET, Feb. 19th, 1921.

ACUTE AND CHRONIC DISEASE.

The clinical classes under which these cases fall are those in which acute disease arises anew and those in which it arises in one who already has chronic disease. The former must be considered under two heads—cases which are seen during the very acute stage and cases which are seen in the less acute stage where the marked symptoms are passed, but the condition has not quite quieted down. In the former, where the illness has lasted over-night or up to 48 hours, the important fact is whether the drum-head is intact or not. When the drum-head is intact decision may be delayed unless the general condition of the patient is such that he appears too ill for a simple otitis media to cause the symptoms. Let it be thoroughly understood that delay in decision must only be countenanced where a careful watch can be put upon the patient. If he be not in a place where you or someone else can keep a watch upon him it is your business to get him there. Delay here may be more readily allowed, because there is a surgical procedure which can be done which has often wonderful results. Again I refer to puncture of the drum-head. The height of the temperature alone is no indication to operate; the case with the highest temperature may recover after puncture and other appropriate treatment; that with a relatively low temperature may already have osteitis of the mastoid; nor is a mastoid tenderness which is limited to the area of the antrum an absolute indication to do an operation, for with suitable treatment this may pass away in the course of a night. It is the persistence of the temperature and of the tenderness over a period of time in spite of treatment which constitutes the important symptom. When the drum-head is already ruptured decision is more difficult and less delay allowed. It means, in all probability, either that the infection is more acute or that the attack has already lasted a longer time. The height of the temperature is now more important, for the relief of the tension should have brought in down; tenderness also is more important, for the same relief should have made it better; and if the tenderness is not limited merely to the area of the mastoid antrum it is a stronger indication to operate. There is another symptom which now may help, the profusion of the discharge. If this is very profuse one can hardly imagine it to be secreted entirely by the lining of the middle ear, and so we may infer that it must come from the mastoid region and look upon it as a point in favour of interference.

It is possible to make a mistake as to decision under two conditions, when one sees a case in consultation on a single occasion and when one is daily in charge of the case, seeing it from time to time. In those cases that I have just considered, he who sees the patient on a single occasion has the harder task. It is a careful consideration of the symptoms from hour to hour over a short time that is the determining factor. In the next class of case, however, the man who comes in afresh with unbiassed mind will often be in a position to make a better decision than he who has been constantly in charge of the case. When the acute stage has passed it is a question of how long without operation you will allow the case to go on before it recovers or subsides into a chronic otitis media. I think these include the most difficult cases of all. The temperature may entirely subside, there may be no tenderness when you examine the patient, he may not complain of pain, and yet the improvement of the general condition may hang fire, and the patient not pick up as he should; or again, there may be a suspicion of some tenderness one day which was not there the day before, and is gone again upon the next; there may be a story of slight earache and no physical signs to account for it; there may be headache due to inflammation of the deeper parts of the bone with the pain referred to the vertex or the occiput. Each one of these symptoms may be insignificant in itself, but if two occur at once I consider them of marked significance. The temperature is now most important. If it does not settle down absolutely, or if having settled down it springs up again all is not well. We must remember that a slow extension of the disease brings it each day nearer to the lateral sinus, and that we have no way of knowing how far that is from the mastoid cavity, nor what sort of bone lies between them. A subsequent rise suggests some invasion of the blood stream, and a series of slight pyrexial attacks is very likely to be followed by a rigor and a thrombosed sinus if left without operation.

When the acute attack follows on chronic disease it is easy to argue thus: "Here is a case in which the possibility of operation had to be considered in any case, let us then do it now and operate on the acute disease and do a radical operation at the same time." It is a fallacious argument, and I do not find that such cases are so likely to do well. The acute disease on the top of the chronic may be more dangerous in that the old disease has already approached the other structures, but it is less likely to be so acute or so rapid, and so the same principles may be adopted in this as in the former class. A bulging of the postero-superior wall of the external meatus is often said to be a definite indication to operation. I am not convinced that this is so, but so many otologists of repute teach this, that it is a sign which cannot be ignored.

There remains those cases in which acute ear disease is associated with other acute disease. I have already mentioned the question of diagnosis, but that does not cover every case. There is still a class in which the ear disease is intercurrent or a distant complication of some other acute disease. Here the decision as to operation is most important. Two things are to be considered, how ill the patient is and whether the ear or the other condition is the more serious. If the mastoiditis is the cause of the most serious symptoms an operation may be necessary whatever the risk, but if the other lesion is so endangering the life that an operation might turn the scale, then you may have to refrain from an operation on the mastoid and take risks of meningitis or sinus infection that would not be justifiable under ordinary circumstances.

SUPPLY OF MILK FOR MOTHERS AND INFANTS.—The Minister of Health announces that owing to the excessive expenditure of many local authorities he has reconsidered the arrangements to be observed as a condition of his sanction to schemes for milk-supply and of grants in aid of expenditure thereon. In order to enable the expenditure to be more effectively controlled former orders have been rescinded and local authorities must in future obtain the sanction of the Minister, under the Maternity and Child Welfare Act, 1918, to schemes for the supply of milk to expectant and nursing mothers and children under 5. In a circular issued to local authorities a list of conditions is given without which sanction will not be given; these limit the quantity supplied at less than cost price to one pint a day (exceptionally one and a half pints for infants between 3 and 18 months) and the recipients to nursing mothers, expectant mothers in the last three months of pregnancy, and children up to 3 (exceptionally up to 5) years of age. The other conditions are framed to ensure that only those applicants receive milk at less than cost price to whom a supply is essential on grounds of health and who cannot afford to buy sufficient milk for their needs.

THE TOXÆMIC STAGE OF DIPHTHERIA

WITH SPECIAL REFERENCE TO PATHOLOGY AND TREATMENT.

BY M. ESTHER HARDING, M.D., M.R.C.P. LOND.,
WILLIAM GIBSON RESEARCH SCHOLAR.

SINCE the introduction of antitoxin the mortality and morbidity of diphtheria have decreased enormously. Patients suffering from mild or moderately severe diphtheria at the present time, provided they receive antitoxin early—in the first three or four days of illness—and in adequate dosage, recover. And, further, the duration of illness and of convalescence are much less protracted than formerly, while late sequelæ such as paralysis and long-continued cardiac weakness are avoided.

There occur, however, many cases of a much more serious type which are seen from time to time at most infectious hospitals, and are all too frequent in certain areas where an epidemic of diphtheria seems to rage perpetually. Many of these patients die in the period between the fourth and the eleventh day of illness—sometimes before antitoxin has been administered and sometimes in spite of massive doses of serum. Other cases survive this first danger period of the disease to drag through a long and critical illness which may terminate in death as long as 12 weeks or more from the date of the infection. Convalescence, if it occurs, is protracted, paralysis is frequent, and cardiac weakness may remain to hamper the patient for years, although ultimate recovery is the rule. During the first week or ten days of an attack of diphtheria of this most severe type the patient shows certain clinical and pathological signs which differ from those of the second stage of the disease, a stage dominated by cardiac (or possibly tissue) degeneration. These phenomena are dependent on an overwhelming toxæmia. I have, therefore, called it the *toxæmic stage* of the disease. It gradually merges into the second stage, that of cardiac weakness.

In the present paper I propose to consider the toxæmic stage of the most severe type of diphtheria only, excluding from the discussion cases complicated by laryngeal involvement. I have been studying the pathology of this phase from the clinical and experimental standpoints since 1917 and during the last year have been investigating certain indications for treatment. I am not at present in a position to test the treatment clinically and am publishing my results with the hope that some investigator with clinical material available may be able to give the method a fair trial. My results are exceedingly suggestive, but are not absolutely conclusive. The failure to obtain a conclusive series of experiments is, I am convinced, due to the fact that I was only able to give part time to the work, with the result that many factors could not be controlled. In order to carry out a satisfactory series of experiments it would be necessary to arrange for a day and a night attendant for the animals.

Clinical Condition of Patient in the Toxæmic Stage of Diphtheria.

The clinical condition of a patient in the toxæmic stage of diphtheria closely resembles that of a patient suffering from wound shock or from the results of a severe hæmorrhage. My object has been to investigate this condition. I found that a considerable amount of work had already been done by previous workers. A summary of their observations and conclusions will be found in my monograph.[2] As the work progressed it became evident that the pathology of the shock-like condition of diphtheria resembled in part the condition in wound and toxæmic shock which was being worked out by the special committee appointed by the Medical Research Council. Up to this time (1917), although it was generally accepted that death in the toxæmic stage of diphtheria was due to failure of the circulation, different opinions were held as to the cause of the failure. Many observations were on record regarding the condition of the heart, the blood-vessels, the blood and the vaso-motor system, each of which had been blamed in its turn as the cause of death in this stage of the disease.[1] The facts had not, however, been correlated in such a way as to present a continuous picture of a series of pathological events leading up to, and culminating in, death from circulatory failure.

My clinical observations showed that there is in this stage of the disease:—

1. A reduction in the cardiac output as indicated by the blood pressure changes.[3]
2. A condition resembling slight œdema, which I have called "lymph-logging."[4]
3. An increase in the specific gravity of the blood. This increase in the concentration of the blood is so severe as to indicate that a large part of the fluid portion of the blood must have leaked out of the blood-vessels. As there is in these severe cases no increase in the flow of urine (generally in fact there is an oliguria) and no diarrhœa we must conclude that the fluid has leaked into the tissues or tissue spaces and probably accounts for the condition of lymph-logging described above.[5]
4. Changes in the suprarenals were also found regularly in patients dead of diphtheria.[6] The changes were of two types: first, hyperchromatism—an increased staining of the nucleus and deeply stained granules in the protoplasm, giving the cell a very active appearance; and secondly, hypochromatism. In some of the cells this change had progressed to an actual chromatolysis, and in some there was a dissolution of the nucleus and breakdown of the cell. These changes were sometimes found side by side in the same section and in every case the changes were very patchy. It is significant that such changes should be present in diphtheria. The persistent low blood pressure of the disease, after the toxæmic stage has passed, may perhaps be related to adrenalin deficiency in part, even if in part it is dependent on long-continued myocardial weakness. After an attack of diphtheria patients complain for many months of lassitude and lack of energy, while the pulse remains "collapsing"—i.e., the systolic blood pressure is normal and the diastolic pressure low, the second heart sound at the base is accentuated, and the heart rate rises unduly on slight exertion. These are also the characteristics of sub-adrenalism. (Compare Addison's disease.)

It seemed that if any progress was to be made as regards the pathology of this condition and its treatment experimental methods must be used which were not applicable clinically.

For, first, in clinical diphtheria the dose of toxin is dependent on the severity of the infection and cannot be varied at will. Secondly, patients are not seen until they are already ill, so that normal readings are never available for comparison, and readings during illness have to be compared against an average for normals of the same age, which may give a very considerable margin of error. Thirdly, diphtheria of the type I wished to study generally occurs in young children who are very ill, so that it may be impossible to get blood specimens and other records as often as desired. And, fourthly, it did not seem justifiable to try a new treatment clinically without evidence that it was at all events harmless experimentally.

Preliminary Experiments on Cats with Toxin.

Experimental work.—For the preliminary experiments I used cats. Cats were chosen because Brodie had found them suitable in studying the effect of diphtheria toxin and because they are satisfactory animals in which to make blood-pressure records with a kymograph.

The toxin I used was supplied by the Wellcome Physiological Research Laboratory. I should like to take this opportunity of expressing my grateful thanks to the superintendent, Dr. R. A. O'Brien, for so kindly providing it. The toxin had been standardised for guinea-pigs: it was of such a strength that—

0·002 c.cm. killed a standard guinea-pig in 147 hours.
0·005 „ „ „ „ 40 „
0·01 „ „ „ „ 27 „

I wanted to give cats such a dose that if they were untreated they would die on the fourth day—i.e., between 96 and 120 hours after inoculation. If the susceptibility of cats is comparable to that of guinea-pigs the dose should lie between 0·002 and 0·005 c.cm. per 250 g. of body-weight. There may possibly be two fallacies in this line of reasoning: (a) cats may be either more or less susceptible to diphtheria toxin than guinea-pigs (unfortunately I was unable to find any records of the dose that Brodie used); and (b) the length of the survival period after a lethal dose of toxin in guinea-pigs is not in direct arithmetical relation to the size of the dose.

I hoped that it would be possible to find a dose of toxin for a standard weight of cat such that it would invariably kill on the fourth day. I arbitrarily chose 2150 g. as my standard body-weight, and tried the following doses:—

A. Dose of toxin per 2150 grammes of cat.
B. Number of hours after inoculation at which death occurred.

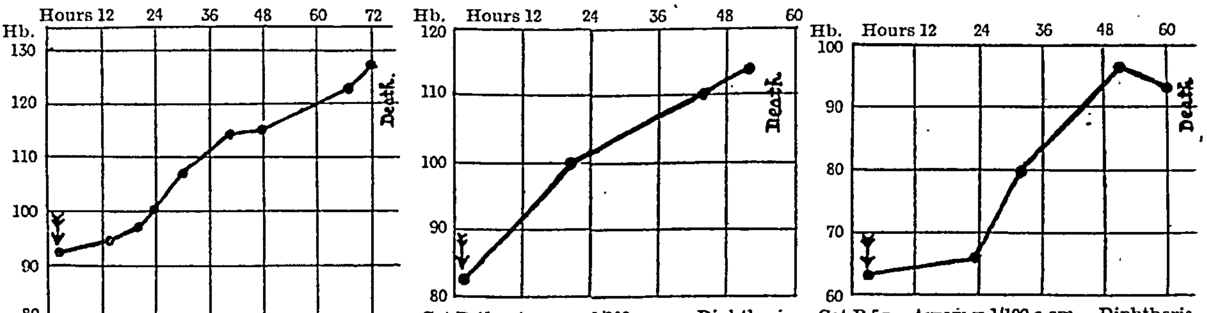
A.	B.	A.	B.	A.	B.
1. 0·66 c.cm.	29	4. 0·02 c.cm.	66	7. 0·02 c.cm.	72
2. 0·1 ,, ...	22	5. 0·02 ,, ...	36	8. 0·01 ,, ...	60
3. 0·02 ,, ...	48	6. 0·02 ,, ...	40	9. 0·01 ,, ...	60

The susceptibility of different cats varied so greatly that it made it very difficult to get records at the most favourable moment, especially as the animals nearly always became ill in the early morning. In many cases they appeared quite well at 8 or 9 P.M., and were moribund by 9 the next morning.

The inoculations were given subcutaneously. A latent period of varying length occurred during which the cat seemed well, although there was some rise of temperature. During the greater part of this period no concentration of the blood was detected. The cat then became lethargic and the concentration of the blood was found to be rising. Certain of the cats were anæsthetised at this stage, and blood pressure records taken. The animals all showed a fall in systolic pressure with a small cardiac output. As death approached the blood pressure fell still further; the right heart was inadequately filled; and the blood concentration reached a high point. In one instance heart-block occurred. In the end the animals rather suddenly collapsed and died.

The condition of the blood as regards concentration was estimated by readings of the hæmoglobin and the specific gravity. Concentration of the blood began towards the end of the latent period and continued to progress until death. The rise in the hæmoglobin percentage was very marked. It was estimated that somewhere about half the plasma fluid must in some cases have been lost from the effective circulation. In one case a vital red estimation was made which showed a loss of just under half (21/44) the plasma volume. (See charts.)

Charts showing Increase of Concentration of the Blood during Fatal Diphtherial Intoxication in Cats.



Cat B 1. Arrow = 1/50 c.cm. Diphtheria toxin.

Cat B 4*b*. Arrow = 1/100 c.cm. Diphtheria toxin.

Cat B 5*a*. Arrow = 1/100 c.cm. Diphtheria toxin.

Thus there is, related to the failure of the circulation which causes death in diphtheria, a reduction in the volume of the blood in circulation. The heart has an insufficient diastolic return; the beat output is reduced and the blood pressure falls. This condition is known to occur in wound and in histamine shock.[7] In these conditions an intravenous injection of a fluid that will stay inside the vessels helps to tide the circulation over the critical period. The problem of treatment in the case of diphtheria is complicated by the myocardial degeneration and the question of whether the heart will be able to work against an increased load. There is of course a second side to the problem. It is uncertain to what extent the myocardial degeneration is a direct outcome of poisoning by the toxin and to what extent it is due to the result of hampered metabolism dependent on the poor circulation. Would it be possible by improving the circulation to prevent in any degree the tissue degeneration which has been considered a specific effect of diphtheria toxin? We know that changes in the myocardium can be produced by soaking a strip of heart muscle in toxin,[8] so that it is unlikely that the tissues can be protected entirely by treating the circulatory failure. But the effect of the treatment described below, in safeguarding the suprarenals, appears to promise that patients treated by this method may have less severe and less prolonged damage to the myocardium and other tissues than patients treated merely on orthodox lines.

Experiments in Treatment.

The experiments so far described indicate that treatment must consist in increasing the fluid in effective circulation and at the same time, if possible, in diluting the blood so as to reduce its concentration and viscosity. The difficulty was to find an innocuous fluid which would remain inside the blood-vessels. For the original loss of fluid showed that either the vessels were unduly permeable or that the osmotic tension outside them was increased. Further, even if the vessels were not damaged directly by the toxin, yet the stagnation of the circulation, obviously present in severe diphtherial toxæmia, would undoubtedly result in damage to the endothelium with increased permeability.

Normal saline.—This was the first solution tried.

Experiment B II.—A male cat, weight 2150 g., was inoculated subcutaneously with 1/10 c.cm. toxin. Twenty hours later the hæmoglobin had risen from 78 per cent. to 108 per cent. and the specific gravity from 1052 to 1056. The animal was practically moribund. It was anæsthetised with ether and a cannula put into the carotid artery to record the blood pressure. The artery was, however, empty and collapsed. The heart was then exposed. It also was empty and fibrillating. 50 c.cm. of normal saline were run into the femoral vein and artificial respiration started. A second intravenous injection of 50 c.cm of saline was given 10 minutes later. The blood pressure now recorded 54 mm. of mercury and gradually rose to 74 mm. After this it fell to 54 mm., then to 44 mm., and then fell about 12 mm. every five minutes. During this time the blood began to concentrate again. Immediately after the second saline transfusion the hæmoglobin reading was 72 per cent. and the specific gravity 1045. The concentration then increased, so that when the blood pressure was 44 mm. the hæmoglobin was 82 per cent. and the specific gravity 1052. Thus the blood again lost fluid; presumably the saline leaked out of the vessels into the tissues.

This experiment showed that by increasing the blood volume, and at the same time reducing the concentration of the blood, the circulation could be improved, but that the effect was only transitory as the fluid was rapidly lost from the vessels with a return to the previous high concentration of the blood. It was therefore concluded that normal saline would not give any increased survival rate after a heavy dose of toxin. This conclusion is in accord with clinical experience.

Gum saline.—The effect of the intravenous injection of gum saline was next tried in the hope that the colloidal solution might be retained in the circulation although simple saline was rapidly lost. Experiment B III. was done on the same lines as Experiment B II. described above, but with gum saline, with a similar result. There was a latent period after the injection of the solution before the rise of blood pressure, which was probably related to poorness (slowness) of the circulation. It was shorter for the second injection than for the first. In each case, as the blood pressure rose and the circulation improved, the cat began to come round from the anæsthetic and the ether had to be increased, with a dependent fall in blood pressure. In this case there was no definite evidence of further leakage of fluid from the vessels. The experiment failed to show that treatment with gum saline is curative, first, because the experiment was done in such a way that the animal could not be allowed to survive, and second, because the animal was already too ill when the injections were given. Two experiments were therefore devised to avoid these objections. Cats were inoculated with toxin and when they showed the characteristic signs of toxæmia gum saline was run into the saphenous vein, exposed by a small incision under cocaine. (These two experiments were kindly performed for me by Dr. H. H. Dale.) Cat B IV.b died 12 hours after the injection—i.e., its life was not definitely prolonged as a result of the treatment. In the case of Cat B IV.a, two injections of gum saline were given. The cat died three hours after the second injection, 15 hours after the first. Blood specimens taken from both these animals showed marked agglutination of the corpuscles, and in both the kidneys were found to be much congested—the glomeruli being full of agglutinated blood corpuscles.

Citrated blood.—The agglutinating effect of gum saline on cat's blood corpuscles seemed to be undesirable in animals with circulatory failure of this type, so citrated cat's blood was tried in the following experiments. The blood was obtained from healthy cats. The animals were anæsthetised and bled out from the carotid artery into citrate solution. The blood was kept in the cold and used as required. It was found, however, that blood so kept rapidly acquired toxic properties and for this reason the method had to be discarded. Owing to difficulty in obtaining cats in larger numbers it was not possible to use a fresh donor for each injection.

Baginski states[9] that there is in diphtheria an increased *coagulability* of the blood. This statement is entirely at variance with the observations made during my series of experiments. I found that the coagulation-time of blood drawn from animals showing increased blood concentration as a result of diphtherial intoxication was prolonged. In some cases the blood showed no trace of clot at the end of half an hour, although it was in contact with tissue juice, and some specimens of blood cleanly collected were not clotted an hour after being shed.

Post-mortem Changes Observed.

The changes observed in the heart and liver were similar to those occurring in clinical cases. The liver suffers more severely in cats than in human beings. Frozen sections stained with Scharlach R. showed no evidence of fatty degeneration. In addition to the change in the heart and liver the suprarenals, also, were regularly found to be affected. They were swollen and unduly pink; in many instances hæmorrhages were present on the surface and in the cortex. The tissue was friable and degenerate. The microscopic changes were very similar to those described below in rabbits.

Conclusions Drawn from Preliminary Experiments.

1. That diphtherial intoxication produces a concentration of the blood in cats with a concurrent fall of blood pressure.

2. That the concentration can be alleviated temporarily by the injection of normal saline into the venous system, a measure which also raises the blood pressure.

3. That the fluid so introduced fails to relieve the condition permanently and concentration rapidly recurs.

4. That injections of colloidal solutions (gum saline and citrated blood) failed in the case of cats for extraneous reasons.

5. That inoculation with diphtheria toxin does not satisfactorily reproduce the conditions of clinical diphtheria.

Experiments with Cultures of Klebs-Löffler Bacilli.

It seemed probable that the concentration of the blood and the failure of the circulation could be more satisfactorily treated in animals infected with the Klebs-Löffler bacillus. For when a lethal dose of toxin is given it is given in one dose, and its effect cannot be overtaken by treatment. But clinical diphtheria develops gradually, the toxin being absorbed continuously in dilute solution. Animals not being susceptible to infection of the mucous membranes with diphtheria bacilli, must be infected by injection. H. G. Savage[10] tried repeatedly to infect cats with diphtheria bacilli on a mucous surface, but failed to produce a condition in any way resembling clinical diphtheria of the type I wished to study. He found, however, that by injecting a broth culture of diphtheria bacilli subcutaneously into kittens intoxication, with death, frequently followed. The doses he used, with very variable results, are as follows:—

—	Age of kitten.	Culture.	Dose.	Result.
1	4 weeks.	24 hours in broth.	2 c.cm.	*Death in 5 days.*
2	2 months.	2 days " "	1·8 c.cm.	*Recovery.*
3	5 weeks.	5 " " "	2 c.cm.	*Death in 9 days.*

Cats were available only in small numbers, and owing to the variation in susceptibility it seemed advisable to try experiments on a larger scale with a considerable number of controls. Rabbits have the advantage of being easily obtained in large numbers; intravenous injections can be made into the ear vein of a rabbit much more readily than into the saphenous vein of a cat; and, moreover, blood for injection can be obtained from a normal rabbit without inconveniencing it. In the following experiments I kept a batch of normal rabbits from which samples of blood were obtained as required.

The Technique Used.

The results obtained by Savage were very variable, and, moreover, broth in which diphtheria bacilli have been grown contains toxin in weak solution. As I wanted in my experiments to reproduce as nearly as possible diphtherial infection as it is seen in human cases, I decided to grow the bacilli on agar slopes and inject an emulsion of bacilli in normal saline. An animal infected in this way differs from an infected human in one other respect. In the human subject the diphtheria bacilli grow on the surface, and as antibodies collect in the blood, either as a result of the administration of antitoxin or from the reaction of the patient, the membrane containing the bacilli is shed and the infection terminated, leaving only an intoxication to be dealt with by the patient. In the case of animals infected by injection the offending organisms cannot be thus shed, so that the animal is at a disadvantage as compared with the human patient.

For each experiment an agar slope was inoculated with one loopfull of growth from the stock culture and grown for 18 hours. The whole of this subgrowth was then transferred to a mixing-tube and thoroughly broken up in a measured quantity of saline by the help of glass beads. A proportion of the emulsion was inoculated into the animals. In this way I avoided giving appreciable amounts of toxin.

The culture used in the following experiments was obtained from a severe case of laryngeal diphtheria. The bacilli, which were in pure culture, were of medium length. 2000 units of antitoxin were given to the animals intravenously when it was judged that the toxæmic stage had advanced so far that antitoxin alone would not save the animal's life.

The injections of bacilli were given subcutaneously on the back in 4 experiments (32 animals); subcutaneously on the inner side of the thigh in 1 (4 animals); subcutaneously on the abdominal wall in 2 (48 animals); and intramuscularly into the thigh muscles in 1 (36 animals). The inoculations on the back were the most satisfactory. The culture was too virulent when given intramuscularly, and in several cases where the injection was given on the abdominal wall the local lesion was found post-mortem to have extended through to the peritoneum and omentum.

Results of Preliminary Experiments with Injections of Cultures.

The first five experiments of Series C were undertaken to determine: (1) whether concentration of the blood occurs in rabbits as it has been shown to do in cats and in man, and (2) what dose of culture is suitable to be sure of killing, but not to kill too soon. It was found that the blood changes were similar to those occurring in cats inoculated with diphtheria toxin. And it was further found that healthy animals, apparently similar, reacted very differently to equivalent doses of culture, while any pre-existing morbid conditions—e.g., coccidiosis, congestion of the lungs, &c.—rendered the animal far more susceptible to diphtherial poisoning, and thus accentuated the actual variability.

Experiments in Treatment.

After these preliminary experiments a series of seven experiments was undertaken to try the effect of treating the deficiency of the circulation by infusion of:—

1. Hypertonic saline (vide Sir Leonard Rogers's work on cholera).[11] A 1·3 per cent. solution was used.

2. Gum saline (vide work on wound shock).[11] 0·6 per cent. gum acacia in normal saline was used.

3. Citrated blood (vide work on wound shock).[11] 3·8 per cent. sodium citrate in water was used; 20 c.cm. of this solution were added to 80 c.cm. of blood—i.e., 0·76 per cent. of sodium citrate in the blood mixture; 0·5 is just sufficient to prevent clotting. The blood was obtained in the case of cats by bleeding the donor animal from the carotid artery under ether anæsthesia. Care was taken that the blood should fall directly into the citrate solution, so that it might be as little damaged as possible. In the case of rabbits donors were kept and bled as required by merely pricking one of the veins of the ear and allowing the blood dropping from the puncture to fall into the citrate solution.

112 blood transfusions were performed on rabbits. No evidence was obtained suggesting that rabbits are grouped like human beings as regards their blood affinities. No ill-effects were noted traceable to the blood as such; in no case was there evidence post-mortem of agglutination of corpuscles, and in one instance only of hæmolysis. This animal died 24 hours after the last blood injection. It showed no ill-effects at the time, and post-mortem the only sign was some pink tinting of the pericardial and peritoneal fluids. Mixed blood was sometimes used, and where animals were given more than one transfusion different donors were used on each occasion.

The seven experiments of Series C were all of the same type.

Typical Course of the Experiments.

The typical course of the experiment was as follows:—

The animals were kept in quarantine under observation for a fortnight before the experiment was started. The number of animals used varied in different experiments from 6 to 36. (The actual numbers were: 18, 36, 24, 24, 6, 6, 6 = 120.) The animals were weighed and their hæmoglobin value estimated. They were then injected with the previously determined dose of culture. As a rule no obvious change occurred during the next 24 to 36 hours. They then became rather lethargic, sometimes refused food, and occasionally had diarrhœa. The hæmoglobin value by this time was found to have increased. A little later the rabbit would sit hunched up in the bottom of the cage. At this stage of the toxæmia it will not move spontaneously, and crawls rather than hops when stirred up. It takes no food. The ears are cold and the eyes dull. There is often diarrhœa. When the ears are inspected the veins show as thin black lines. If one of the lateral veins is punctured no blood exudes. The cross veins are invisible. If the ear is warmed and rubbed with ether or xylol the lateral veins become a little better filled. If the blood is pressed out the vein collapses and fills again only very slowly. But after the ear has been warmed for some minutes the vein fills with brighter coloured blood. As death approaches the circulation becomes more and more stagnant. In many instances it was impossible to obtain samples of blood for the estimation of hæmoglobin, and the attempt to do so caused such damage to the veins that intravenous injections were even more difficult than they would otherwise have been. In the ear veins it is possible actually to see the improvement in the circulation due to local warming, and it may be surmised that warmth applied generally to the whole body surface would have a similar effect on the general circulation. In certain instances where the animal suffered from fainting or convulsions it was found that warmth applied to the thorax by holding an electric lamp close to the chest wall had a restorative effect, and several of these animals finally recovered.

When it was judged that the intoxication had progressed far enough the animals were divided into groups. Often certain of the animals had to be discarded as dead or dying. The control group was treated with a single intravenous dose of antitoxin only. The animals in the other groups, in addition to a similar dose of antitoxin, received infusions of one of the fluids described above (hypertonic saline, gum saline, or citrated blood) at intervals of 12 hours—two, three, or four injections being given in the different experiments. The immediate good effect of intravenous transfusions was very striking. The solution had to be given very slowly. The circulation through the veins improved visibly during the injection. After the blood or saline had been given the animals became much more lively; they often started feeding or cleaning their fur. This effect was seen even in rabbits which eventually succumbed. In certain cases, however, where the animals were in extremis before the injection was given bad effects resulted. In some cases the animal fainted or had a convulsion, while, in a few, death followed either with or without a previous convulsion. The most effective treatment for this collapse was found to be warmth and elevation of the feet. In each instance where death occurred in this way the circulation was very stagnant and the blood dark and tarry. The fatal effect may be due to a washing out into the general circulation of accumulated metabolic products. If such is the explanation, death is due in these cases to an acute toxæmia from metabolic products, and indicates that the circulation should be improved to the greatest possible extent by warmth, &c., before giving an intravenous injection, and that the fluid should be given *very* slowly. Another possible explanation of these sudden deaths is to be found in the degenerate state of the heart. It is possible that the sudden rise of blood pressure due to the increase in blood volume is just too much for the heart in its weakened state. This hypothesis also indicates that the fluid should be injected slowly and that struggling should be prevented.

The Amount of Fluid Injected.

As it had been estimated that animals in a profound state of diphtherial toxæmia had lost a very large proportion of the fluid part of their blood it was considered essential to give large injections of fluid. A normal rabbit of 1100 g. weight (which was the average size of the animals used in these experiments) is calculated to contain from 80 to 100 c.cm. of blood. For the first injection I gave from 15 to 20 c.cm. of citrated blood together with about 5 c.cm. of antitoxic serum. The subsequent injections were 10-15, 10, and 5 c.cm. respectively. These are large injections, 20 c.cm. being equivalent to one-fifth of the total volume of blood the rabbit would have in the normal state. If the animal had lost about a third of its blood fluid an injection of this size represents about two-thirds of the defect.

Post-mortem Changes.

In the animals which died, both those from the control groups and those which died in spite of intravenous treatment, the local site of infection was found to be the seat of hæmorrhagic necrosis. In the animals treated with antitoxin only, the changes in the organs were similar to those already described in cats and human beings. In those animals which had been treated with blood transfusions and yet had succumbed there was one pronounced difference in the post-mortem findings. The suprarenals in the untreated animals, and in those treated with antitoxin only, were large, dark-coloured and hæmorrhagic, while in animals treated with blood transfusion in addition they were little, if at all, enlarged and normal in colour.

The suprarenals of two animals which died on the same day, as a result of infection with diphtheria bacilli, were taken and compared as regards size, weight, and colour. The first animal, *rabbit C.X. 2*, had been treated with blood transfusion as well as with antitoxin; the other animal, *rabbit C.X. 5*, had been given antitoxin only.

The suprarenal of the blood-treated case appeared to be about normal in size. The dimensions were: length 0·75 cm., breadth 0·4 cm., thickness 0·18 cm. The suprarenal of the untreated case was much larger. The length was not greatly increased, being 0·85 cm.; the breadth was definitely increased, being 0·7 cm., while the thickness was nearly doubled, 0·3 cm. The weight of the gland from the treated case was 0·052 g., and of that from the untreated 0·115 g. The colour of the gland from the treated case was a normal yellowish pink. That from the untreated one was of chocolate brown, and its tissue was very friable.

Microscopic changes.—(1) Frozen sections stained with Scharlach R. No fatty degeneration detected. (2) Material hardened with bichromate solution and stained with hæmotoxylin and eosin. Suprarenals prepared by this method stained very patchily. The cells of the cortex showed degenerative changes of varying degree. In the treated cases certain areas were made up of cells with deeply-stained nuclei and granular protoplasm, and other areas had pale nuclei with only skeleton cell outlines. The blood-vessels were congested. *In untreated cases large areas of hæmorrhage* were to be seen under the capsule and scattered through the cortex. The areas of degenerate cells were larger and the degree of degeneration more pronounced. The cells were separated from one another so that the tissue looked much more open than in the normal state. In all the specimens the medulla was small and shrunken. This change was most marked in the untreated cases. The chromaffin bearing cells were often deeply stained, the granules of chromaffin sparsely scattered and small. In many cases the medulla showed as a mere slit or line when the section was examined naked eye or with a hand lens. (3) Fixed with Carnoy's solution. This method of fixing was used to determine whether the irregular staining was not possibly due to excess of water in the cells and tissue spaces (compare lymph-logging). Sections of suprarenals fixed by this method shrank more than normal tissue would do. Sections fixed with Carnoy's solution took the stain much more evenly than the other preparations and the cells were not so widely separated, but the other features were still present—i.e., in the cortex the nuclei showed in some parts hyperchromatism with a granular cell protoplasm, and in other places hypochromatism, and in other parts were mere skeletons.

Late Changes in Surviving Animals.

In two instances where the culture had been given intramuscularly paralysis of the limb inoculated developed six and a half weeks after the injection. It finally disappeared entirely. Where the culture had been given subcutaneously a slough developed at the site of the inoculation. This was eventually shed, generally about the fifth week. (These animals had all been treated with blood transfusions.) Many of the animals treated with blood transfusion recovered. Animals recovering generally seemed to be normal by the eighth day. The first experiment of this series was the most successful. Eighteen animals were inoculated and four were treated with blood transfusions. Of these four, three survived, while the other animals, some untreated and some treated with antitoxin, without exception died. Details are as follows:—

Experiment C. VI.—Animals: 18 rabbits; weights from 1000 to 1800 g. Culture: 18 hours on agar slope. Dose: 1/18 of total slope in 0·5 c.cm. saline. Site: Subcutaneous, on back in 14 animals; on inner side of thigh in 4 animals.

Summary.—Of 18 animals injected with diphtheria culture 5 died on the second night and a fifth was discarded as very ill. The remaining 12 were divided into three groups, care being taken to arrange that the animals of the different groups were as nearly as possible comparable as regards degree of illness.

Group A.—Nos. 13, 14, 17. 18 received no treatment. Nos. 13, 17, and 18 died on the fourth day. No. 14 died on the eighth day.

Group B.—Nos. 6, 7, 11, 12 given antitoxin intravenously on the third day and no further treatment. No. 7 died on the fourth day. No. 12 died on the fifth day. No. 6 died on the sixth day. No. 11 died on the eighth day.

Group C.—Nos. 2, 3, 4, 5 given antitoxin intravenously on the third day and intravenous blood transfusions on the third day (20 c.cm.), on the fourth day (20 c.cm.), on the fifth day (10 c.cm.), on the seventh day (5 c.cm.). No. 5 died on the evening of the fourth day. Nos. 2, 3, 4 recovered and remained normal.

I had hoped to confirm this result by a further and conclusive experiment, but for various reasons the subsequent attempts were not so successful. The results of one experiment were nullified by the culture being given intramuscularly, by which route it proved much more lethal. In another the dose was too small; a third was vitiated by an epidemic of pneumonia amongst the animals; and in a fourth the animals died as a result of the weather turning suddenly cold.

In spite of these untoward circumstances, the results of the experiments show definitely that a certain proportion of animals suffering from diphtherial intoxication of such severity that if treated with antitoxin alone they would surely die, will, if treated also with blood transfusions, recover.

Conclusions Derived from Experiments.

There were no more survivals in the groups treated with hypertonic saline or gum saline, together with antitoxin, than in the control group treated with antitoxin alone. These animals have therefore all been considered together in contrast to those treated with blood transfusions and antitoxins.

Twenty-four animals which were inoculated and treated had to be discarded as the dose was sub-lethal, several of the controls surviving. A series of 95 animals received a lethal dose of diphtheria bacilli. Thirty-two of these were treated with blood transfusions in addition to antitoxin; of these, 15 survived the eighth day and 12 recovered entirely. Thirty-five were treated by antitoxin alone or by hypertonic saline or gum saline in addition; of these, 6 survived the eighth day and 5 recovered entirely.

Intravenous injections of citrated blood in addition to antitoxin treatment have not, in my hands, infallibly saved animals infected with a lethal dose of diphtheria culture. Indeed, they could hardly be expected to do so. Yet a certain number of animals which otherwise would certainly have died did actually recover as a result of the treatment. Further, in those animals which died in spite of blood transfusions it was found post mortem that the suprarenals had suffered less severely than in cases treated only with antitoxin.

It is safe to conclude that in clinical diphtheria treatment along these lines will probably reduce the risk of death—i.e., will increase the chance of survival, and by safeguarding the suprarenals will shorten the illness and lighten its severity. If blood transfusions served merely to protect the suprarenals the indication for their use in all very severe cases would be strong. It is probable that clinically a larger proportion of cases of diphtheria equivalent in severity to these infected animals might be saved by this means. For it is not possible to nurse animals as a human patient is nursed, while it is a well-known fact that nursing is a most important factor in saving bad cases of clinical diphtheria.

Suggestions for a Clinical Test of the Method.

1. *The donor of blood.*—Either a member of the staff at the hospital who from previous test is known to belong to group IV. should be chosen, or a relative of the patient can be used. In this case the donor's blood must be tested directly against the patient's. The blood should be collected by putting a needle into one of the veins at the bend of the elbow. If the blood is allowed to fall clear into sterile citrate solution there is no need to use paraffined tubes. The blood must be collected aseptically and should be used at once.

2. *The patient.*—If the patient is a small child it will, in many cases, be necessary to give a general anæsthetic. Antitoxin can be given intravenously at the same time as the blood transfusion. In very bad cases it will probably be necessary to cut down on the vein.

3. *Quantity of blood to be used.*—Amounts equivalent to those used for rabbits in the foregoing experiments are as follows:—

Age of child.	Weight of child.	Quantity of blood.
1 year.	21 lb.	160 c.cm., or ℥ v.
2 years.	2 stone.	200 ,, ,, ℥ vii.
4 ,,	2½ ,,	300 ,, ,, ℥ x.
6 ,,	3 ,,	400 ,, ,, ℥ xiii.

4. *Frequency.*—The intravenous transfusion should be repeated every 24 hours until three or four injections have been given, depending on the severity of the case.

5. *Precautions.*—The precautions usual in giving intravenous injections must be observed. Rigid asepsis must be practised; the fluid must be given at body heat, and bubbles of air must be excluded. The special precautions necessary in cases of diphtherial intoxication are: (*a*) In severe cases the circulation must be improved as far as possible by warming the patient, and by warming the arm where the injection is to be made. This will not only make the actual technique easier, but will reduce the risk of washing out toxic products. (*b*) The fluid must be run in very slowly.

It should be borne in mind that there is a certain risk of washing out toxic metabolic products, and thus giving rise to a rigor, convulsion, or even sudden death. But when it is recalled that such accidents are only likely to happen in cases so severe as to have practically no chance of recovery apart from blood transfusion, the risk can hardly be considered as a contra-indication to the treatment. And if the precautions detailed above are observed even this risk will be reduced.

The experiments were carried out at the National Institute for Medical Research, Hampstead, through the hospitality of the Medical Research Council. I wish to express my thanks to Dr. H. H. Dale for his unfailing kindness and interest in the work, for his many valuable suggestions and practical assistance; and to Dr. W. E. Gye for preparing cultures and for much help in all the bacteriological side of the work; also to Miss Durham and Miss Marchal for practical assistance in many of the experiments.

SOME NOTES ON THE
PROPHYLAXIS OF TYPHUS FEVER.

BY J. M. MITCHELL, O.B.E., M.B., CH.B. ABERD.,
CAPTAIN, I.M.S.; LATE O.C. BRITISH MISSION HOSPITAL, SOUTH RUSSIA;
AND
G. P. N. RICHARDSON, M.A., B.CH. CAMB.,
LATE M.O. ATTACHED BRITISH MISSION, SOUTH RUSSIA.

DURING the recent war typhus fever was, fortunately, quite uncommon in the British Army. Outbreaks occurred in some of the prison camps in Germany, in parts of Mesopotamia and Palestine, and in some of the smaller war areas. It is only, however, since the occupation of Constantinople and the consequent extension of our military activities to Southern Russia that units of our army have begun to suffer any high percentages of casualties from this disease. The present article is based upon our experience in connexion with Russian typhus during the winter epidemics of 1918–19 and 1919–20, and has special reference to those cases which occurred among the members and the attached Russian personnel of the British Military Mission to General Denikin's army.

The numbers of the British personnel of the Mission varied considerably from time to time, but during the winter of 1919–20 they averaged about 1000 men. The corresponding incidence of typhus is shown in Table I.:—

TABLE I. (British Personnel Only).

	1919 Nov.	Dec.	1920 Jan.	Feb.	March.	April.
Admissions ...	3	12	36	21	16	1
Deaths	Nil.	1	7	4	1	Nil.

A total of 89 cases with a mortality of 13 (14·6 per cent.).

Among the Russian population the incidence of the disease and the death-rate were both considerably greater than this, and the result was a very widespread epidemic which finally completed the disorganisation of the South Russian Army and of the country. As the epidemic progressed the advance of the enemy became more and more rapid, and the influx of refugees from the conquered territories made the overcrowding problem increasingly more acute. Towns which had normally 100,000 inhabitants were suddenly compelled to make room for 500,000, and houses which had formerly contained one family now housed anything up to ten. The station waiting-rooms and public buildings were packed with refugees who made these places their homes, and it was no uncommon thing to find numbers ill with typhus lying amongst the healthy.

The causes of this disaster may be summed up in the statement that it was entirely due to inefficient prophylaxis and lack of understanding of the essential features of the disease. Epidemics of considerable severity had been experienced during the two preceding winters. It was not sufficiently recognised, however, that, at any rate as far as Russia is concerned, typhus is a winter disease. There are two reasons for the winter prevalence, one being that owing to the cold weather personal cleanliness is at a low ebb and lousiness becomes almost generalised, and the other that the cold increases the overcrowding and the number of contacts to every case. For these reasons the epidemic of the winter 1919–20 might reasonably have been predicted during the previous summer and preparations made to combat it, but very little was done. Russian soldiers were not usually provided with a change of clothing, and baths were difficult or impossible to obtain. Inspections for lice and the disinfection of clothing and blankets were not often undertaken. Such disinfecting plants and bathing establishments as there were in the towns were mostly out of work because they were insufficiently supplied with fuel.

General prophylaxis on British lines was practised as far as possible among the personnel of the British Mission. At the British hospital a very strict regime was practised; all patients on admission had their hair closely cropped, were bathed and sponged all over with methylated spirit, and were put into entirely fresh clothing before being taken to their wards; all the nursing staff wore gowns in the wards, and had very frequent baths and changes of underclothing. During the retreat, when the hospital was on the move, this regime could not be carried out in its entirety, but every effort was made to keep any potentially infected clothing separate. It was during this period that the only case of typhus which occurred amongst the medical orderlies was contracted.

It will, however, be clear that the value of such general prophylaxis as this was very greatly diminished by the fact that the members of the British Mission were daily coming into contact with large numbers of people who adopted no such precautions. It was therefore quite insufficient to prevent a serious epidemic of typhus among the British.

Attempts at Specific Prophylaxis.

Apart from the general prophylactic measures indicated above some trial was made of the specific prophylaxis of the disease by inoculation and encouraging results were obtained. Although several organisms have been described none has yet been definitely proved to be the cause of typhus. Nicolle has, however, shown that it is very probable that the causal organism is to some extent localised in the leucocytes of the blood. This assumption is the basis of the method of preparation of most of the vaccines which have been used in Eastern Europe during the past few years. The vaccine used in South Russia during the winters 1918–19 and 1919–20 was of a crude type and consisted essentially of sterile typhus blood free from fibrin. It was prepared as follows:—

The apparatus for the collection of the blood consisted of a glass bottle containing a few pieces of glass and plugged with wool through which passed a glass tube connected with a needle suitable for intravenous work. The whole was sterilised and 6–8 oz. of blood were collected in the bottle from a suitable vein. The blood was defibrinated by shaking and was allowed to stand for two or three days. It was then again shaken up and 2 per cent. of carbolic acid was added. The resulting fluid was then transferred to and sealed in suitable ampoules which were heated for one hour at a temperature of 57°–58° C., after which it was used as a vaccine in the usual way.

The patient selected as the donor of blood must fulfil the following requirements:—

(1) He must be free, as far as ascertainable, from other disease.

(2) He must be on the first, second, or third day of the rash—i.e., usually on the fifth to seventh day of illness. Patients who have reached a later stage than this are unsuitable owing to the possible existence of a septicæmia due to complications such as parotitis.

Three doses of the vaccine were given in the arm subcutaneously or intermuscularly at intervals of five to seven days, the amounts being 1 c.cm., 2 c.cm., 2 c.cm. No general reaction was observed.

During November and December, 1919, 195 of the Mission personnel were fully inoculated in this way. Of these typhus subsequently developed in one only (0·5 per cent.). The number of the Mission not inoculated or not fully inoculated at this time was about 800, and amongst these typhus subsequently developed in 89 (11 per cent.). The one person who developed typhus after complete inoculation was a Russian nursing sister attached to the British Hospital. She came into contact with infection by visiting friends in Russian hospitals, but did not contract the disease until three months after inoculation.

The personnel of the British Hospital and of the Tank Corps Detachment (a mobile unit living in trains for the most part and travelling about the country) were fully inoculation almost without exception. Among the R.A.M.C. hospital personnel the only case of typhus was in a man who had received two doses only of vaccine. Among the Tank Corps personnel the only case was in a man uninoculated. A certain number received only one or two injections. Exact figures are not available. Amongst these several cases of typhus occurred, one, in particular, very severe; but none died. Amongst those who contracted typhus after inoculation or partial inoculation the mortality was nil.

The above figures refer to the inoculations which were performed at the beginning of the 1919–20 epidemic in November and early December, 1919. Later in the epidemic, in February, 1920, further inoculations were performed by practically the same method. At this time two persons received one injection each while in the incubation period of typhus. The possibility of infection at the inoculation could be excluded. Both developed very severe attacks (with marked nervous symptoms, and so confirmed the Russian experience that if a patient in the incubation period is given a dose of vaccine, or if he contracts the disease during the negative phase after a dose of vaccine, the severity of the attack is increased. This would point to the conclusion that if prophylactic inoculation is to be done it should be done before the disease has become epidemic. Otherwise it would possibly decrease the total number of cases, but might even increase the mortality.

Our results are summarised in Table II. :—

TABLE II.

Inoculations.	No.	Contracted typhus.	Mortality.	Remarks.
Full 3 injections.	195	1 (0·5%).	Nil.	Contracted typhus 3 months after inoculation.*
2 injections.	?	3	Nil.	One leg lost from gangrene.
1 injection.	?	15	Nil.	—
1 injection during the incubation period.	2	2	Nil.	Severe nervous symptoms.
Not inoculated.	700–750	69	13 (18·8%).	—

* Course of disease and recovery normal.

The fact that the only case which occurred amongst all the fully inoculated developed three months after the inoculation would point to the prophylactic being good for a short period.

A Dangerous Test.

An interesting experiment was undertaken by Dr. I. N. Asheshov, a Russian bacteriologist working at the British Mission Hospital. Three weeks after taking a prophylactic injection of 5 c.cm. of vaccine he inoculated himself subcutaneously with 1 c.cm. of blood taken direct from a typhus patient on the fifth day of his illness. This patient developed a very severe attack of typhus with a hæmorrhagic rash and died on the fourteenth day. On the afternoon of the thirteenth day from inoculation Dr. Asheshov felt unwell and the temperature rose. A severe attack of typhus developed and a hæmorrhagic rash began to appear on the second day. For about a week the patient's condition was fairly well maintained, but then collapse began to set in. Salines were given subcutaneously, and on the ninth day a first dose of 10 c.cm. of antityphus serum was injected intravenously. This was repeated on the two following days, and after the third dose a marked improvement in the patient's condition took place. The pulse-rate decreased from 160 on the 9th day to about 120 on the 11th. The temperature, which had fallen to below 101° F., again rose to a more normal level for this stage of the disease (104°). The temperature fell by lysis about the 14th day, and recovery took place. Convalescence was very slow, and at the end of three months he was only able to get about slowly. This may be in part accounted for by the very unsatisfactory conditions of the retreat which took place about this time. He had to be moved four times in the fortnight following the defervescence, once within 24 hours of the crisis in a Russian blizzard and twice in an open cart. This experiment was probably of too severe a nature, as such a heavy dose of the infecting organism as may be considered to be present in 1 c.cm. of blood could probably never be introduced under normal conditions by lice.

Conclusion.

Although the results mentioned above are suggestive, it cannot be said that the prophylaxis of typhus by inoculation has yet been placed on a firm basis. Further observations on a more extensive scale are necessary, and a fair trial should be given to this method in all countries in which typhus epidemics occur.

A FATAL CASE OF
CŒLIAC INFANTILISM

WITH COMMENTS ON THE MORBID ANATOMY OF CŒLIAC DISEASE.

BY REGINALD MILLER, M.D. LOND., F.R.C.P. LOND.,
PHYSICIAN TO PADDINGTON GREEN CHILDREN'S HOSPITAL;
PHYSICIAN TO OUT-PATIENTS AND CHILDREN'S OUT-PATIENT DEPARTMENT, ST. MARY'S HOSPITAL.

AUTOPSIES on cases of cœliac disease have been so seldom recorded that it seems advisable to publish the details of even a single case. In the present paper I give the particulars of a fatal instance of cœliac infantilism to which I have alluded in recent communications on cœliac disease,[1,2] and comment on the present and previously reported autopsies, with special reference to their bearing on the cause of the malady.

History of Case.

H. B., born March, 1913; fourth child in family of four, others strong and healthy. Born at full term; weight 8 lb. Breast-fed for two months; when weaned feeding difficulties appeared, and different foods were tried, but on each there was a tendency to looseness of the bowels. Later he attended various hospitals; it was noticed that "cod-liver oil did not suit him." He was late in walking.

1915.—Brought to my out-patient department at Paddington Green Children's Hospital for the first time in June, aged 2¼ years. The mother stated that the diarrhœa had been worse for six months, causing wasting; the motions were pale and very offensive and the abdomen enlarged, at times markedly so; swelling of the hands, feet, and eyelids developed from time to time. It was also stated that the child was very languid, preferring to stay in bed, and craved for tasty food, pickles, and vinegar, and would eat dirt. He would not readily take milky foods. On examination the abdomen was found to be prominent, but nothing abnormal could be felt within it. A provisional label of "? Abdominal tuberculosis" was given. In July the child was admitted for the diarrhœa under one of my colleagues, but was discharged a week later slightly relieved.

1916.—Not seen again until April. It was now stated that he had ceased growing for six months. The diarrhœa had been worse, again accompanied by swelling of the extremities, wasting, and occasional vomiting. For the rest of this year he attended me as an out-patient and was treated for the most part with bismuth and opium, which partially checked the diarrhœa. Exacerbations of it occurred in April, May, and December.

1917.—In January and February the diarrhœa was again worse, but with out-patient treatment it remained rather better until September. In October he was admitted for a second time under a colleague. He was then stated not to have grown for 12 months. The abdomen was large but showed no evidence of tuberculosis. The stools were large, pale, fatty, very offensive, and typical of cœliac disease. He had no stomatitis at any time. In hospital and convalescent home the diarrhœa lessened, but he gained neither in weight nor height. In December he returned to my out-patients, his motions remaining loose.

1918.—Not seen again until Oct. 1st, when he was brought to me again for severe diarrhœa. He was readmitted, coming under my own care as an in-patient for the first time.

He is now aged 5½ years. His height is 35½ in. (normal for age about 41½ in.); weight 24½ lb. (normal for age about 40 lb.). He has not grown for two years, wearing the same sized boots as two years ago. In stature he looks between 2 and 3 years old, but his facial expression is more corresponding with his real age. He is thin, but not at all marasmic, his face and anterior abdominal wall are the fattest parts of him. His colour is fair. His first teeth have been extracted for caries, but his first upper molars have already appeared. There is no evidence of osseous rickets. His manner is "old-fashioned" and that of a chronically invalided child. His abdomen is large, but no masses or matting can be felt within it. The bowels act several times a day and perhaps four times at night. The motions are large, pale, unformed, very offensive, and characteristic of cœliac disease. There is very little colic, except occasionally just before an action. Very slight dorsal clubbing of the fingers is present. The right knee-jerk is very difficult to obtain, the left is not obtained.

Course.—He was given a mixed diet, low in fat, containing skimmed milk, which was later replaced by Horlick's malted milk. Bynopancreatin was given with meals. During four weeks in hospital he lost 10 oz. in weight, though the diarrhœa lessened to some extent. He was then sent to the hospital's convalescent home at Slough.

For three weeks he appeared to be doing well there and improving. On Dec. 20th he was suddenly taken with fever and very severe diarrhœa, passing blood and mucus in his motions. He collapsed and died within 18 hours. Two other children before and seven others after him had similar illnesses, and the epidemic was regarded as one of influenza showing abdominal symptoms. There were no other deaths.

Autopsy.

Post-mortem examination was made by me 60 hours after the child's death. The body was not wasted, the subcutaneous fat being fairly plentiful in amount; it was thicker on the abdominal wall than elsewhere. No evidence of tuberculosis was found anywhere in the body. Tongue and tonsils normal. Thymus small. Heart and lungs normal. Liver: Weight 14½ oz.; not obviously fatty. Gall-bladder and duct appeared normal. No note was made on the character of the bile.* Pancreas and duct normal. Spleen: Weight 1¼ oz., normal. Kidneys: Weight 1¼ oz., each, normal. Suprarenals: Extensive hæmorrhage into the substance of the left gland, disorganising it; small areas of hæmorrhage into right gland, which otherwise appeared normal. Omentum: There was a copious deposit of omental fat sufficiently marked to strike me at once as peculiar in a child. Stomach normal. Intestine: Peyer's patches slightly enlarged; walls of intestine not thinned, seeming the normal thickness. There was injection of the mucosa of the colon, increasing from above downwards; no ulceration.

Histological examination (for this I am indebted to the kindness of Dr. E. H. Kettle, pathologist to St. Mary's Hospital).—The specimens showed slight post-mortem changes. Liver: No fatty or other change. Pancreas: Gland substance not altered by post-mortem change; normal in amount and appearance; no cell infiltration nor increase of fibrous tissue in the gland. Pancreatic and common bile-ducts show no chronic inflammation. Spleen and kidneys normal. Suprarenals: Hæmorrhagic changes, leading to disorganisation of the gland substance. Intestine (small and large at various levels): The mucosa shows much superficial post-mortem desquamation, and no opinion can be given on its condition at death; the deeper layers show no evidence of cell infiltration or fibrosis, and the examination satisfactorily excludes the presence of chronic inflammatory changes in the small intestine and colon.

To summarise, the patient, a boy, died at the age of 5½ years, of influenza. He had suffered from cœliac symptoms for nearly five years, had been under my observation for over three years, and was conspicuously stunted in growth. At the autopsy no chronic changes to account for the protracted symptoms were found in the liver, pancreas, intestine, or elsewhere.

Comments on Present Case.

1. *Interpretation.*—It is clear, I think, that the injection of the mucosa of the intestine, and the hæmorrhage into the suprarenals found post mortem, were the result of a terminal infection. This was not merely an exacerbation of the cœliac symptoms but a complicating and separate condition. This is proved by the facts that it was an epidemic infection (the patient was the third in a series of ten cases arising within a few days of each other), and that the symptoms it produced, notably the presence of blood and mucus in the stools, were different from those of cœliac disease, as it had shown itself in this patient. In spite of the presence of slight changes of decomposition it was possible to recognise that the gland substance of the pancreas and liver showed no evidence of disease. As far as the intestine was concerned the examination only served to exclude chronic changes such as might be expected to be present if cœliac disease were due to a chronic enteritis. Of such there was no trace; in particular there could be demonstrated no such cell infiltration and fibrosis as were found in the deeper layers of the intestine by Poynton, Armstrong, and Nabarro.[3]

2. *Inference.*—This case seems to show that cœliac disease, persistent enough to produce infantilism and severe enough to be associated with attacks of œdema of the "alimentary" type, may exist apart from structural changes in the pancreas, liver, or intestine; or, to put it more precisely, that the persistence of the excessive fat-wastage is independent of morbid changes in these organs.

3. *Growth in cœliac cases.*—It is difficult to say why growth is so much more impaired in one case than another. That the lack of growth might be in part due to the development in protracted cases of a secondary enteritis is an obvious and attractive explanation; but while it seems more than likely that the fatty contents of the intestine may set up catarrh of the bowel, the present case in which there had been cessation of growth for at least two years shows that such secondary changes are not necessarily severe nor persistent, and it remains questionable if they are essential to the production of infantilism.

4. *The cœliac abdomen.*—Abdominal enlargement is a cardinal feature of cœliac disease. Distension of the bowel with flatus and fæces and an atonic condition of the abdominal wall are recognised causes of enlargement of and variations in the patient's girth. Ascites has been recorded. But these factors do not altogether account for the chronic enlargement of the abdomen which remains in the most quiescent and convalescent stages of the disease. In one case of mine, for instance, which was gaining weight very rapidly, as the weight ascended and the stools became smaller and more solid the abdominal circumference continued to increase in measurement. In this connexion the copious deposit of fat in the omentum, which was so striking a peculiarity in the present case, becomes of interest, and I suggest that this omental fat and the fat of the abdominal wall together account for the persistent enlargement of the abdomen in such conditions as I am here discussing. Further, I think that they may explain the peculiar "feel" of the abdomen, characteristic though difficult to describe, which resembles that of the abdomen of a plump young adult. And I may here, perhaps, mention that some physiologists have thought that it is the fat derived from the carbohydrates of the diet which is first laid down in the omentum and abdominal wall.[4]

Discussion on Autopsies Previously Reported.

Of the symptoms of cœliac disease, one stands out as of pre-eminent importance—namely, the excessive fat-loss in the stools. Any explanation of the origin of the disease must necessarily explain this essential symptom, and thus attention is directly drawn to the possibility of organic disease of the pancreas or liver interfering with fat-digestion or of the intestine interfering with fat-absorption. Failing to find satisfactory evidence of such organic disease, we are left with the alternative of a functional derangement of the pancreas or liver to account for the disturbed fat-digestion. Having described above a fatal case of cœliac infantilism in which no structural disease of the organs mentioned could be found, I turn now to the study of the views of previous investigators and the pathological evidence already recorded, to see if they support or contradict the findings in my case.

Of actual post-mortem records there are extraordinarily few. Only three have I been able to find in the literature, and of these two are, in my view, very doubtful cases, though, as they have attracted some attention, they require discussion.

Gee,[5] who first described the "cœliac affection" (1888), wrote:—

> "Naked-eye examination of dead bodies throws no light upon the nature of the cœliac affection; nothing unnatural can be seen in the stomach, intestines, or other digestive organs. Whether atrophy of the glandular crypts of the intestines be ever or always present I cannot tell."

Gibbons,[6] the next year, expressed the same opinion. He regarded the disease as due to a widespread functional derangement, probably of nervous origin, of the digestive glands. Cheadle[7] viewed it in much the same light, emphasising particularly the derangement of the liver by describing his cases under the title of "acholia." In 1908 Herter[8] published his well-known book on Intestinal Infantilism. His cases were undoubtedly instances of cœliac disease, the existence of which, as he did not know of any of the previous descriptions, he here rediscovered. His work was of great importance, as he originated the idea that the failure in fat-absorption was the result of the presence of a chronic inflammation of the bowel. This he ascribed to the overgrowth and persistence of certain flora of the infantile intestine. Without always confirming Herter's bacteriological findings, many have adopted his nomenclature as expressing the view of the intestinal origin of the defective fat-absorption in what was in reality cœliac disease. Of these may be mentioned Freeman[9] and also Bramwell,[10] who put into this group such cases as would not fit into the type of "pancreatic infantilism" described by him in 1902.[11] Of all these authors—and many others might be mentioned—not one published the result of a post-mortem examination.

---

* At the time of making this examination I had in mind the possibility of pancreatic disease or the chronic gastro-enteritis described in a paper by F. J. Poynton and others (discussed later), as mentioned by G. F. Still in his Lumleian lectures.

In 1913 Poynton, Armstrong, and Nabarro[8] published jointly, under the title of "A Contribution to the Study of a Group of Cases of Chronic Recurrent Diarrhœa in Childhood," a series of nine cases, of which most read like instances of cœliac disease. Of this series, the very peculiar first case was fatal, and a detailed account of the autopsy is recorded. In 1918 Still,[12] in his Lumleian lectures on Cœliac Disease, alluded to this particular case as "the only detailed record of a post-mortem which I have been able to find," and adds the information that the child was "much below the normal height for his age." He also gives an account of a very similar autopsy on a case of his own. Since this date Moorhead[13] has reported an autopsy on a case of "intestinal infantilism," the first published under this title. These three autopsies, then, seem the only ones that have any bearing upon the morbid anatomy of cœliac disease, and it will be seen that in all intestinal disease was found to be present. I have therefore to consider if these cases prove that the excessive fat-loss in cœliac disease is primarily due to a chronic enteritis preventing fat-absorption.

For the reader's convenience I venture to recall the essential features of the cases of Poynton, Armstrong, and Nabarro,[8] Still[12] and Moorhead.[13]

The Case of Poynton, Armstrong, and Nabarro.

A. H., male, died at 9 years. At 1 year had an attack of diarrhœa and abdominal swelling lasting eight months. At the age of 5 he came under authors' observation for the first time. He had then had diarrhœa for three months, at times passing blood and mucus. From that time (1908) until his death in 1912 he had repeated attacks of diarrhœa. At first the stools were noted as large, light brown, soft, and offensive, and were regarded as denoting a condition of chronic colitis. It was not until 1911 that the stools were reported as "white"; in the next year they were described as suggestive of cœliac disease. In the earlier stages the patient was treated by rectal lavage, milk diet, and bismuth and opium. In 1910 it became apparent that the "condition was gaining on the patient," and on each readmission to hospital he appeared worse. In 1911 he was treated by appendicostomy and lavage of the colon, and made much improvement for a time. Nine months later he became extremely ill, collapsed, and died. Still adds the information that the child's growth was much impaired.

Autopsy.—The macroscopical features are summarised thus: "(1) Thickening of the walls with inflammatory changes affecting the entire alimentary canal; (2) the absence of striking changes in Peyer's patches; (3) the absence of any obvious pancreatic lesion; (4) the abnormality of the liver, which was large and very fatty, the absence of any evidence of tuberculosis." Microscopically the alimentary tract showed congestion of the mucous membrane, with congestion and small round-celled infiltration in the submucosa and increase in the perivascular fibrous tissue in the muscular coat. In the colon these changes were less marked than in the small intestine and stomach. The liver showed universal and severe fatty changes. The pancreas showed that the interlobular fibrous tissue was much increased, particularly that surrounding the ducts. Bacteriologically a "dysentery bacillus of the Flexner group differing from the type bacillus in only a few minor points" was grown from scrapings of the mucosa of the colon. The heart's blood gave growths of *B. coli* and streptococci" (regarded as terminal or post-mortem infection).

Summary of case by Authors.—"This case is an extremely interesting one, because clinically it was regarded as one of colitis with recurrent acute attacks, without its dysenteric nature having been established. Post mortem the condition of the large bowel closely resembles that of patients in asylums who have suffered from subacute or 'periodic' dysentery."

Comment.—In spite of Still's comment on this case it is, I think, impossible to regard it as one of cœliac disease, unless that term is to mean no more than a fatty diarrhœa in a child. Certainly the authors did not so regard it at the time of publication. On the contrary, they went out of their way to avoid the term, as witness the title of their paper, and they gave clearly enough their interpretation of the case when they stated that they think it "justifiable to suggest that we have two factors to consider—the possible occurrence of a peculiar infection and the appearance of special symptoms of the cœliac affection as a sequel, but not necessarily as a constant occurrence." They considered the intestinal disease, diagnosed during life as chronic colitis, as responsible for the recurrent and persistent diarrhœa, while they suggest that the excessive fat-wastage in the stools which appeared late in the course of the disease may have been due to the severe fatty degeneration of the liver. With the latter suggestion it is not easy to agree, but there is no difficulty in accepting the view that the case was primarily one of chronic enteritis. This, which appears to have been a chronic dysentery of the "asylum" type, ran a relentless course; it interfered with the child's growth (producing a true condition of "intestinal" infantilism) and gradually made the child more and more ill. After some years an excess of fat appeared in the diarrhœic stools. Rather than attribute this to the fatty degeneration of the liver I suggest that this late symptom may have been due either to the enteritis becoming sufficient of itself to interfere markedly with fat-absorption or to the pancreatitis set up secondarily to the enteritis.

The point which I particularly desire to emphasise here is that this case does not demonstrate (and was not thought by the authors to demonstrate) any essential connexion between cœliac disease and enteritis; still less does it prove that the excessive fat-wastage in cœliac disease is due to a failure of fat-absorption owing to disease of the intestine.

Still's Case.[12]

The author writes:

"Clinically, the diagnosis had been in question on account of the unusually rapid course and also the comparatively late age at which the symptoms began. A boy aged 7 years was under my care 19 weeks with looseness of the bowels, amounting at times to actual diarrhœa. He had been sent into hospital as a case of tuberculous peritonitis on account of wasting and enlargement of the abdomen, but one early began to doubt this diagnosis, for the stools at times were suggestive of cœliac disease, and, moreover, there was, with œdema and purpura, frequently recurring tetany. .... On the ground that the case was probably one of cœliac disease, the boy, after several weeks of unsuccessful treatment, was put upon a fat-free diet and at once improved greatly, as cœliac cases usually do upon such feeding, but a few weeks later had a relapse of looseness with much distension of the bowel and died of exhaustion."

The autopsy showed changes in the intestine and pancreas similar to those recorded in the last case by Poynton, Armstrong, and Nabarro, but the liver was not fatty. No bacteriological examination was made at the autopsy; during life a bacillus resembling in many respects the *B. lactis aerogenes* was grown from the fæces.

Comment.—Apart from the marked clinical peculiarities of the case considered as one of cœliac disease the author is not disposed to assert with any assurance that the intestinal changes account for the excessive fat-wastage. "It is," he writes, "at least conceivable that the whole inflammatory process might be secondary to some functional failure of digestive secretion." It would seem to me that the explanation of this case might well be one similar to that already suggested for the one quoted above—namely, an enteritis with a secondary failure of fat-absorption due either to the intestinal disease or to the consequent pancreatitis. It does not seem possible to regard the case as proving the association between the ordinary case of cœliac disease and enteritis in the sense that the latter is the cause of the essential cœliac symptom of excessive fat-loss in the stools.

Moorhead's Case.

I have already stated that this is the first account of an autopsy published under the title of "Intestinal Infantilism," and that this term was invented by Herter, when he "rediscovered" cœliac disease, on the assumption that an enteritis was the primary cause of the fatty stools in his cases. In the present case, if we assume that the character of the stools was of the same fatty type throughout the illness (which the author does not actually state) it would appear that we have a most interesting example of infantilism arising from true cœliac disease. The only question then needing discussion is concerned with the author's view that the intestinal lesions found post mortem were the primary cause of the fatty diarrhœa.

Girl, aged 18 years, height 4 ft. 5 in., weight 3 st. 9 lb. She showed no secondary sexual characteristics. The history stated that at first healthy, she developed diarrhœa at the age of 5, and that this persisted and became so severe that at the age of 10 she ceased to grow. Under observation the motions were frequent, large, yellowish-white, and offensive; microscopically they showed large numbers of fatty acid crystals, a few undigested muscle fibres, and great quantities of the ova of *Trichocephalus dispar*. The abdomen was small, the liver and spleen palpable and slightly enlarged. The knee-jerks were absent. There was a trace of albumin in the urine. She suffered much from muscular cramps and attacks of tetany. She died of tetany and coma, following an apparently mild attack of influenza.

Autopsy.—The thymus was enlarged, the uterus atrophic, and the ovaries consisted of fibrous tissue only. The spleen, liver, pancreas, kidneys, and suprarenals were normal. The pituitary showed some changes thought to be secondary to inanition. "The small intestine showed marked post-mortem changes; the villi showed no structure and most of the surface portion of the mucosa had disappeared. Marked catarrh of the intestine was present, desquamated cells and mucus lay on the surface, and most of the cells of the glands showed goblet formation. The condition, in fact, was that which Herter surmised must exist." A microphotograph of the colon is reproduced.

Comment.—The author states that "the apparently primary pathological change in this case was catarrh of the colon, and probably also of the small intestine, and in consequence one may regard the case as one of undoubted intestinal infantilism." But it is not easy to accept this view. Clinically we have in this case, as I understand it, a fatty diarrhœa lasting for 13 years, and so severe as to produce a practical cessation of growth for eight years; post mortem there are found intestinal changes which are too acute and trivial in type to account for so chronic and severe a condition, and, moreover, they affect chiefly the colon, which has no part to play in fat-absorption. It is, I think, very much more plausible to regard the intestinal condition as not the primary cause of the fat-wastage, but as a secondary condition arising from result of the excess of fat in the intestinal contents and the infection by whip-worm.

If this view be accepted the origin of the excessive fat-loss in this case remains, as in my own, undiscovered by the post-mortem examination.

Conclusion.

A detailed consideration of these three autopsies in which intestinal lesions were found shows that they fail to prove that the excessive fat-loss in cœliac disease is due to an enteritis. This view is supported by other considerations. The excessive fat-loss in the stools is the essential and characteristic feature of cœliac disease. It is the first diagnostic symptom to appear, and is of severe grade (up to 57 per cent. of the fæces may consist of fat). It is altogether out of proportion to the disturbance in protein digestion. In all these features cœliac disease is unlike an enteritis.

The following recent case seems definitely to prove that the essential fault in fat-absorption is not merely the result of an enteritis.

G. W., female. At 2 years developed very offensive diarrhœa with enlargement of abdomen. Did not walk until 4. Ceased growing from 7 to 10. Then symptoms ceased and growth restarted. I first saw her at 10½ years, when she was 6 in. below normal height. For 11 months, during which she grew 1½ in., I watched her, awaiting a return of the diarrhœa. She was taking ordinary diet and no special medicine. As no further diarrhœa developed I had an analysis made of her fæces in order to test the reality of her "recovery." The stool was dark brown, formed, hard, and appeared normal. Nevertheless, when dried it was found to contain no less than 39·6 per cent. of fat (neutral fat, 7·0 per cent.; fatty acid, 28·3 per cent.; soaps, 64·7 per cent. of total fæcal fat). No excess of protein was found microscopically.

Again, so far as symptoms denoting enteritis are present they are usually late in the disease, as Still[14] observes. We do not in a typical cœliac case watch an enteritis becoming so severe as to cause conspicuous fat-loss in the stools; rather we seem to see a case essentially one of defective fat-digestion in which mild symptoms of intestinal catarrh may develop. That this is the generally accepted view is shown by usual treatment advised—namely, a fat-free diet.

On the other hand, the autopsy which I have reported here confirms the absence of organic disease which was emphasised by the original writers on the affection. If this be taken as a correct view, it follows that the defective fat-absorption in cœliac disease must be due to a fault of digestive secretions, either of the pancreatic juice or of the bile. Of these it is practically certain that the pancreas is not to blame,[1] and there is some evidence that the essential fault in cœliac disease is concerned with the bile-salts.

Summary.

1. Details have been given of a fatal case of cœliac infantilism in which post-mortem examination failed to show any chronic changes in the pancreas, liver, intestine, or elsewhere to account for the prolonged failure in fat-digestion.

2. The only autopsies hitherto recorded in cases of at all a similar nature have been discussed in detail; and it has been argued that the intestinal changes found in them do not prove that the excessive fat-loss in cœliac disease is due to an enteritis.

3. Other reasons against the view that cœliac disease is essentially an enteritis have been given.

4. From these arguments it is concluded that cœliac disease is independent of organic changes and thus must be due to a digestive fault (probably a defective action of the bile on fat-absorption).

RECURRENT HERNIA:

THE OPERATIONS FOR ITS CURE.

BY A. W. SHEEN, C.B.E., M.S.LOND., F.R.C.S.ENG.,

VISITING SURGEON, MINISTRY OF PENSIONS HOSPITALS, ORPINGTON AND SHEPHERD'S BUSH; CONSULTING SURGEON, KING EDWARD VII.'S HOSPITAL, CARDIFF, ETC.

I HAVE operated recently on a number of cases of recurrent inguinal hernia, a few recurrent for the second time. The previous operations have been done in hospitals of various kinds—large civil hospitals, army hospitals, and smaller hospitals often described as "V.A.D.," "auxiliary," or "country house." It may be presumed that the experience of the operators varied considerably. The histories given by the patients suggest that in nearly all the cases the hernia was quite small at the original operation; the recurrence also has been, almost invariably, small. Several times I have diagnosed the "recurrence" wrongly as direct hernia. In only one case has there been evidence of wound infection; operators have been able to maintain asepsis and recurrence has not been due to weak post-suppuration scars. The original operation incisions have been short, not extending far out; the musculo-aponeurotic structures have shown evidence of repair, but the region of the "neck" of the sac has remained apparently virgin ground. The joining of the conjoint tendon to Poupart's ligament has been often shown by the "pegging" of muscular fibres into the ligament. The cord has in a few cases been superficial to this—i.e., a Bassini operation has been done, but much more frequently behind, in its normal position. In some cases possibly the tendon-ligament junction has given way and the cord has sunk back. In one case the vas alone was subcutaneous and might easily have been cut, the other structures of the cord being normally placed. In another a hydrocele of the cord was found, which appeared to be due to leaving the distal part of the sac. In another the original operation was for strangulated hernia. In some cases a direct hernia was present, although whether the original operation was for direct or indirect hernia it was impossible to say. In one case there was a double direct hernia. I have not seen direct evidence of ligation of the sac-neck, but sometimes there has been much scarring on the inside or outside of the sac. Neither have I seen gliding hernia or hernia demonstrable as being within the one horn left of an original bifid sac. It has often been puzzling or impossible to determine exactly what the original operation was. The matting of the parts frequently renders the operation difficult and tedious.

Causes of Recurrence.

The conclusions I have arrived at are: that in indirect hernia the usual cause of recurrence is non-removal of the deeper part of the sac; that an occasional cause may be a small sac not having been found; that other recurrences are those of direct herniæ; that in a few cases an original indirect hernia has been cured, but a direct hernia has been present at the original operation or has developed subsequently. I have seen a number of cases of recurrent hernia in which the patients, naturally disappointed, have refused further operation and asked for trusses.

There must be an enormous number of hernia operations; operators count their cases by hundreds, sometimes by thousands. No major operation is, I imagine, more frequently performed. The percentages of recurrences I do not know; recently working in two hospitals I have encountered a number; every hospital surgeon must be operating on them, so that the total number is great. The recurrence in my cases after an original operation for small hernia is to be noted; these should be the most successful cases.

What can be Done to Lessen the Number of Recurrences?

In the first place, it must be recognised that a well-performed hernia operation demands a high degree of technical knowledge and skill, and that no one should attempt it who has not been thoroughly trained by actual operative experience on the living body. I remember—almost with horror—many years ago being interviewed by a candidate for a certain hospital appointment, who most ingenuously said that he would like to have a "slap at a hernia"! Those of us with larger experience should recognise that the deepest part of the sac right down to the parietal peritoneum must be removed to effect a cure. Recurrences—particularly immediate—may be due to the treatment of an indirect and the overlooking of a direct hernia. Sometimes a hernia operation only reveals a very tiny indirect sac beneath the internal oblique margin, the class of sac which is frequently found incidentally in a very high operation for varicocele; the operator should then be especially careful not to miss a direct hernia.

The Operation for Recurrent Hernia.

In operating for recurrence, whether I think the hernia is indirect or direct, I always investigate both possibilities. I first seek for the sac in the region of the internal ring, as that is the easiest place to find it. After reaching the external oblique aponeurosis I incise it from the external ring for 3–4 inches and turn back the flaps. I then open the cord coverings close to where the internal oblique edge crosses over the cord and divide the internal oblique in the line of the canal outwards for about an inch, this being often done between two pairs of pressure forceps placed on the muscle, as there is an artery in the muscle which is thus conveniently controlled. A sac, if present, is found and the outermost part of its neck reached without any retraction. The sac is then followed down and isolated by splitting the coverings and dissecting them off. The sac is then opened and the finger passed inside and hooked round on the peritoneal surface and its point pushed forward against the peritoneum and transversalis fascia on the inner side of the deep epigastric vessels, thereby demonstrating a direct hernia if present and its size, and feeling the width of the gap between the conjoint tendon and Poupart's ligament. The appendix can now often be removed on the right side through the sac opening. Lipomata are removed. Where there is an indirect and no direct hernia the operation is continued by removing the sac flush with the parietal peritoneum (taking care to go deeper than any circular white thickening on its interior wall), and closing the peritoneal wound. Then the cut internal oblique and the coverings of the cord are sutured, the internal oblique and the conjoint tendon drawn down to Poupart's ligament as an additional safeguard, and the external oblique closed. The cord is as little interfered with as possible, and remains in its natural position.

The Bassini Operation.

Where there is a definite direct hernia, with or without an indirect, or where there is a large gap between conjoint tendon and Poupart's ligament, then, after treatment of any direct sac present as necessary, an operation of the Bassini type is performed, the cord eventually lying subcutaneous. I have sometimes found it necessary to put in a wire filigree lying on the transversalis fascia. I think the Bassini type of operation unnecessary in ordinary cases, the small herniæ which, nowadays, form the majority of cases operated on. Neither am I enamoured of the disturbance of the cord nor of its being placed between sutured planes or subcutaneously. Still, I think the operation should be that of choice for large musculo-aponeurotic weaknesses and for direct herniæ.

The operative procedures I have described are the ordinary ones I use for hernia. The division of the internal oblique I regard as essential in adults to get at the "neck" of the sac properly. It is not, however, necessary in babies, where the tiny overlap of this muscle can be ignored, and where the operation can be simplified to a complete removal of the sac in a way that has often been described.

An Illustrative Case.

I conclude with an illustrative case, selected because I made full notes of the operation immediately after its performance.

W. W. S., aged 36, formerly a private in the Labour Corps. A right hernia appeared in 1915 and increased in size until it became scrotal. Two years later he went into hospital for operation on it. Strangulation occurred there; immediate operation. Now there is a short linear scar over the external ring, with slight forward bulging beneath it. He is a fat man.

Operation March 21st, 1921. Long incision. The external ring was enlarged, with bulging below it, in which a few scattered cremaster fibres were seen. A small incision through this thin scar tissue opened an intimately adherent sac. The thin external oblique aponeurosis was incised for four inches and turned back, thereby disclosing a fat-overlaid internal oblique. The aponeurosis was scarred in its lower part. The internal oblique was cleared on its deep surface and divided for one and a half inches between two forceps; its section showed much fat intermingled with the muscle. The "sac" was then laid freely open and found to end blindly above and below, forming a large cyst without fluid in it, lined by shiny peritoneum, through which vas and veins could be seen. The cyst extended below into the upper part of the scrotum, but was separate from the tunica vaginalis; above it ended near the internal ring. Projecting into its upper end from the internal ring was the true sac, the size of a pigeon's egg, on the wall of which at its upper margin the cyst ended. Two layers of peritoneum had therefore to be gone through to reach the interior of the hernial sac. I cleared this sac near the ring, the rest of it being free, and continued the separation half an inch beyond the commencement of the parietal peritoneum, dividing deep to its neck a knot of scar tissue, probably the place where the strangulating stricture was divided. The sac had been opened during these manipulations; non-adherent omentum occupied it. The finger was passed within it and inwards, demonstrating that there was no direct hernia, and that the parietes were firm, the conjoint tendon coming close down to Poupart's ligament. The sac was removed and the peritoneal wound closed. The large cyst was removed. A large lipoma running along the cord was removed, being tied at the level of the peritoneal wound in two sections. The vas and other cord structures were freed and held aside. All fragments of cremaster, other coverings, and scar tissue were cleared off conjoint tendon and Poupart's ligament. The internal oblique and conjoint tendon were joined to Poupart's ligament, two stitches going external to the cord. The external oblique was closed. The cord was laid back and the subcutaneous fascia and skin united over it.

Comments.

At the operation for strangulation the external oblique was opened for an inch or more from the ring, the sac opened, the stricture divided, the contents reduced, and the wound closed, healing per primam. Adhesions closed the neck of this original sac and a second sac was invaginated into it from the top, originating either from the deepest part of the original sac beyond the closing adhesions or as a new sac. No "radical cure" was done. It is advisable that it should be done in operations for strangulation; usually there is no additional risk. The second operation shows that conditions present can best be elucidated by approaching the neck of the sac first. The Bassini type of operation was done although there was no great musculo-aponeurotic weakening because of the fatty condition of the muscles and the weak scar in the external oblique.

SECTIONS OF NEUROLOGY AND OPHTHALMOLOGY.

Ocular Palsies.

Two evenings were set apart by these sections of the Royal Society of Medicine for a discussion on Ocular Palsies, at which the chair was occupied alternatively by Professor E. S. Reynolds and Dr. James Taylor.

Dr. Gordon Holmes opened the debate by a reasoned dissertation on the various forms of palsy met with in eye muscles and the anatomical situation of the causal lesions.

He recommended a careful study of the normal movements of the eyeball, and set out the associated palsies of the muscles which normally act together. An interesting point was the "unwillingness" of a patient with cerebellar disease to turn the eyes to the side of the lesion in performing conjugate deviation, which was met with in some cases of this disease, an important and new observation. Since he had been attached to the Moorfields Eye Hospital he had seen many cases of ocular palsy, and he was always conscious of difficulty in deciding what any case was likely to be due to. Only by a careful weighing of signs of associated disease could a presumptive diagnosis be arrived at. With regard to Graves's disease it was surprising to remember that not many years ago Dr. Hughlings Jackson and others regarded ocular palsies in association with Graves's disease as very exceptional. At Moorfields he (the speaker) saw a considerable number of these palsies in patients suffering from Graves's disease. He had no satisfactory explanation of the fact to offer, and one of the difficulties in determining the nature of ocular palsies was the paucity of careful histological work. In a considerable proportion of the cases of Graves's disease with ocular palsy there was but little proptosis, though he admitted that in some the muscular weakness was due to mechanical conditions. Wilbrand and Sänger stated that the ocular palsies in Graves's disease were usually due to nuclear degenerations. With regard to so-called rheumatic or toxic neuritis of oculo-motor nerves, he had seen a number of these cases, and there was a frequent involvement of the external rectus or of the muscles innervated by the third nerve, associated with pain in the forehead on the same side; sometimes there was considerable anæsthesia. In some of the cases of the kind he had encountered there was a septic focus in the vicinity. It was not yet known what a rheumatic neuritis was. Déjerine and others had found merely degenerative changes in some part of the nerve. It would be difficult to conceive of exposure to cold involving ocular nerves in their intracranial course. He did not feel that these cases were rheumatic nor purely toxic, because most toxic affections were bilateral, or at least more or less symmetrical, whereas most of the palsies were unilateral, or certainly asymmetrical. In the spinal cord local collections of cerebro-spinal fluid formed and compressed the roots of the nerves or the cord itself; similarly he thought loculated collections of cerebro-spinal fluid might form in the base of the brain and there involve one of the oculo-motor nerves. He had seen cases of chronic nuclear palsy. One had weakness and limitation of eye movements in all directions, with bilateral ptosis. The intrinsic muscles were intact. The ocular palsy in this case was associated with wasting of certain other groups of muscles, especially those at the shoulder girdle, of the progressive muscular atrophy type.

Complex Problems of Ætiology.

Mr. Leslie Paton spoke of the complexity of the subject. One disease alone, such as syphilis, could produce oculo-motor paralysis in numberless ways.

It might affect any part of the oculo-motor apparatus—cortical, supranuclear, nuclear, nerve roots, nerve trunks in their intracranial course, in the cavernous sinus, in the orbit, or it might affect the muscles themselves. Syphilis could set up disease of the vessels, and hæmorrhages might occur affecting the nuclei or the nerve roots; or a syphilitic arteritis in the internal carotid might press on nerve trunks in the wall of the cavernous sinus. Similarly an endarteritis might affect the vessels supplying the crura, the mid-brain, or the pons, and produce areas of softening. Or syphilis might give rise to tabes or general paralysis and to the variety of ocular disturbances arising in these diseases. Yet probably not more than 40 per cent. of cases of ophthalmoplegia were due to syphilis. Oculo-motor paralyses were divisible into three main groups: (1) Paralyses of central or cerebral origin. Subgroups of these were supranuclear lesions, internuclear lesions, nuclear, and nerve root lesions. (2) Paralyses of extra-cerebral origin—i.e., of nerve trunks, including intracranial and intraorbital cases. (3) Paralyses of muscular origin. He said the important internucleal set of fibres was in the posterior longitudinal bundle; it was by means of this bundle that the various oculo-motor nuclei were brought into connexion with each other and with the vestibular and auditory functions, also with the general, the muscular, the sense, and other afferent impulses in the body. The most important nucleus of origin of these fibres lay in Dieter's nucleus. The control of the internal musculature of the eye was a matter of considerable doubt. The vascular supply of the oculo-motor nuclei was derived from the anterior end of the basilar artery. Nuclear ophthalmoplegias, or ophthalmoplegias proper, could be subdivided into acute and chronic types. The first included the toxic form caused by alcohol. Wernicke's acute polio-encephalitis superior hæmorrhagica was the best example. Good examples of the infective type of acute ophthalmoplegia were found in lethargic encephalitis, influenza, and syphilis. But in some cases no infective agent could be found. The most important form of chronic progressive ophthalmoplegia was that occurring in tabes and general paralysis of the insane. Some ophthalmoplegias were of congenital origin, others were of a distinct familial type.

Rheumatic and other Toxi-infective Origin.

Dr. Wilfred Harris considered that cases of chronic nervous disease in which there was weakness of one internal rectus in lateral conjugate deviation were not very rare. He had seen the sixth nerve suffer after the injection of the Gasserian ganglion with alcohol. Recovery ensued after about four months. He asked for opinions as to the existence of rheumatic neuritis of the oculo-motor branches of the third or sixth nerve in the orbit. He described cases in which the symptoms seemed very suggestive of rheumatism as the cause.

Mr. Gray Clegg (Manchester) spoke of ophthalmoplegia in Graves's disease. He said that Osler and Macrae regarded the paralyses of ocular muscles occurring in Graves's disease as complications, rather than as part of the main disease. One authority, Suker, said a new ocular muscle symptom was present in a number of cases of Graves's disease—namely, "deficient complementary fixation in lateral eye rotations," he regarding it as due to a dissociation in the functions of the sympathetic and the extra oculomotor nerves of the eye.

Dr. Kinnier Wilson discussed the question of a possible unilateral cranial polyneuritis, which he regarded as one of considerable clinical importance. He described the case of a man severely ill with a general pneumococcal infection, showing itself as pleurisy and pneumonia, and who had complete paralysis of the seventh, eighth, ninth, tenth, eleventh, and twelfth cranial nerves, but on the right side only. There was no involvement of an ocular muscle or ocular nerve in that particular case, but he had seen analogous cases in which the sixth and seventh or the fifth, sixth, and seventh were involved, and saw no reason to doubt their toxi-infective origin.

Mr. N. Bishop Harman remarked on the comparative rarity of the kind of cases now under discussion. In a consecutive series of 5000 cases he found only 27 instances of ocular palsy—17 males, 10 females. Seven were due to injury, five to syphilis, five to general vascular disease or degeneration. Two cases in which the palsy followed exposure might be disputed by the neurologists, but in one of them there were clear manifestations of inflammation over the affected muscle, and both cleared up rapidly. Mr. Harman agreed that, apart from the cases of paralysis due to direct injury to the bones of the orbit and those ensuing on exposure, the occurrence of such a paralysis was a sign of serious general disease, but his own cases did not encourage the view that life was shortened thereby. He gave a careful analysis of his 27 cases. Discussing the treatment, he advocated countering the danger of diplopia by the wearing of one lens of ground glass. When the

lesion was peripheral he found blisters, faradism, and massage were effective local measures.

Progressive External Ophthalmoplegia.

Mr. M. L. **HINE** read a contribution by Mr. W. H. **MCMULLEN** and himself on Chronic Progressive Ophthalmoplegia Externa. Wilbrand and Sänger, in their textbook, grouped as a clinical entity certain cases of external ophthalmoplegia which they considered as having certain definite characteristics to distinguish them from the congenital cases of this affection and from those due to a defined toxic cause or to syphilis, or associated with manifestations of wider-spread disease of the nervous system. It was, however, by no means generally agreed that a separate classification of these was justified. The characteristics associated with them Wilbrand and Sänger gave as: (1) onset gradual, usually in infancy; (2) it is bilateral and very slowly progressive; (3) no other signs of nervous disorder or impaired health; (4) it might come to a standstill at any stage, but generally ended in complete external ophthalmoplegia.—Mr. **HINE** and Mr. **MCMULLEN** showed three patients whose condition illustrated their thesis.

Mr. M. S. **MAYOU** sent a brief description of two cases of paresis of the upward and downward movements of the eyes. The first definitely followed straining at stool. The pupils were active to light and lateral movement was unimpaired; he could converge. Vision was 6/12 in each eye, there was no optic neuritis, and the knee-jerks were present. Downward movement first improved, attempts at upward movement causing a coarse nystagmus. Wassermann was negative. Recovery was now practically complete. The second patient was suddenly seized with intense vertigo and diplopia. Vision was 6/6 in either eye, but the pupils were very sluggish, and he had no power of convergence. Wassermann was negative, knee-jerks present. No other nerve affection could be discovered. Both cases improved on iodide of potassium. In previously recorded cases the position of the lesion had been variously stated to be the optic thalamus, corpora quadrigemina, pons, and subcortical, but there seemed to have been no verification of this by autopsy.

Sixth Nerve Paralysis.

Mr. J. H. **FISHER**, referring to the suggestion that alcohol injections into the Gasserian ganglion sometimes caused sixth nerve paralysis, owing to damage of the nerve in the floor of the cavernous sinus, said he thought that was a rather improbable situation for such an event to take place. He knew of one case of sixth nerve paralysis in which the lesion was not there. The lesion in the cases referred to was not, he thought, in the cavernous sinus, but posterior to it.

Dr. **TAYLOR** said he had always felt somewhat sceptical about paralysis of ocular muscles being of so-called rheumatic origin. Seventh nerve paralysis was very common as a result of so-called rheumatic neuritis, but he had for years watched cases of ordinary seventh nerve paralysis without ever seeing sixth nerve paralysis associated with it. He had hoped to hear more allusion to cases of myasthenia gravis, as that was one of the common grounds on which neurologists and ophthalmologists met. A number of these cases had been referred to him by his colleagues at Moorfields. One of the most astonishing features about them was the great variability in their course, though some progressed steadily downwards. He referred also to a peculiar case in which a man with ocular palsies, double ptosis, &c., but with very little defect in limb movements, in whom the palsies were progressing downwards, so that later he could neither get about nor feed himself, developed an intense desire to return to his home in Hampshire. He went, and the next that was heard of him was in a letter written by himself, asking that the military authorities should be informed that he was not fit for service, as he had had myasthenia gravis.

The openers replied.

During the meeting Mr. J. H. Parsons was congratulated from the chair on his nomination for the Fellowship of the Royal Society.

SECTION OF ANÆSTHETICS.

AT a meeting of this section of the Royal Society of Medicine held on March 5th Dr. H. J. **SHIRLEY**, the President, in the chair, Dr. W. J. **MCCARDIE** read a paper on

Explosion of Ether Vapour During Laryngoscopy.

It occurred in a man of 56, who was given open ether to induce anæsthesia for laryngoscopy and removal of a piece of the vocal cord. For some minutes before the laryngoscope was introduced ether with oxygen was given through a nasal catheter in addition to ether from the mask. The mouth being opened, ether and oxygen still passing in through the nose, Mr. Musgrave Woodman began to introduce Hill's electric laryngoscope. It had not entered more than an inch when there were heard two or three loud reports like small pistol-shots, and flames issued from the patient's mouth. These were 5 or 6 inches high, and like those seen if a Winchester quart bottle of ether is set on fire. The nasal tube was at once pulled out and the flames quickly died. Anæsthesia was continued with chloroform and oxygen without trouble. There was no obvious burning, merely reddening of the mouth and pharynx, and the patient recovered normally and had no after cough. At the time of the explosion the room (temp. 65° F.) was lighted by two ½ watt bulbs and one Osram bulb under a shade 2½ feet away almost directly over the patient's head. The bulb of the laryngoscope light did not fuse, and the light appeared in order and there was no evidence of short-circuiting. No heat could be felt by the hand when the light was first switched on. The warm room, warm mouth, warm electric light, warm ether and oxygen, would all help towards the explosion. Ether vapour would take fire at a considerable distance from the source of heat. Dr. Squibb had related that he had seen ether take fire at a measured distance of 15 feet between the source of escaping vapour and the source of fire. Considering the absolute coincidence of the explosion with the introduction of the lamp, the cause must be found in the electric bulb of the laryngoscope.

Dr. McCardie related the only other recorded case of ignition of ether vapour in the presence of a closed electric light. Other instances of ether vapour ignition were brought forward by members of the section.

Mr. **RAYMOND APPERLY** read a paper on

The Importance of an Examination of Patients by the Anæsthetist Previous to the Administration of Anæsthetics.

The speaker pointed out that improvements in anæsthesia during the last 15 years had been not in the increased number of drugs at our disposal but in the variety of more scientific methods of administering them. This placed on the anæsthetist an increased responsibility in his choice of method. There was still room for improvement both in diminishing fatalities and in reducing after-effects, and one step towards this lay in thorough examination of patients some time before operation. The condition of the cardio-vascular, respiratory, and nervous systems could only be ascertained in this way, as well as the efficiency or otherwise of the kidneys. Previous examination too gave the anæsthetist time to think out the line of action best suited to the individual. Moreover, cumbersome or elaborate apparatus might be required, which would not be present unless the need for it had been appreciated beforehand. The examination was an advantage to the patient, who felt that nothing was being left to chance, to the anæsthetist who might glean important facts for his guidance, and to the surgeon who was able to rely on the anæsthetist's opinion as to the patient's ability to stand a prolonged operation. The physician, who seldom saw an operation, was not so well qualified a guide. The risks which a patient ran were not confined to serious operations. For minor ones they were often grave just because of the slightness of the operation leading to neglect of necessary precautions regarding the anæsthetic. In private practice patents in nursing homes were at hand and could be seen on the day before operation. In hospital practice there was routine examination by house officers and the anæsthetist was supplied with the information acquired. One class of patient, that which was admitted to the cancer department of the Middlesex Hospital, had especially emphasised for us the importance of preliminary examination. Mr. Apperly said that cachectic debilitated persons, often with secondary

OCULAR PALSIES.

Two evenings were set apart by these sections of the Royal Society of Medicine for a discussion on Ocular Palsies, at which the chair was occupied alternatively by Professor **E. S. REYNOLDS** and Dr. **JAMES TAYLOR**.

Dr. **GORDON HOLMES** opened the debate by a reasoned dissertation on the various forms of palsy met with in eye muscles and the anatomical situation of the causal lesions.

He recommended a careful study of the normal movements of the eyeball, and set out the associated palsies of the muscles which normally act together. An interesting point was the "unwillingness" of a patient with cerebellar disease to turn the eyes to the side of the lesion in performing conjugate deviation, which was met with in some cases of this disease, an important and new observation. Since he had been attached to the Moorfields Eye Hospital he had seen many cases of ocular palsy, and he was always conscious of difficulty in deciding what any case was likely to be due to. Only by a careful weighing of signs of associated disease could a presumptive *diagnosis be arrived* at. With regard to Graves's disease it was surprising to remember that not many years ago Dr. Hughlings Jackson and others regarded ocular palsies in association with Graves's disease as very exceptional. At Moorfields he (the speaker) saw a considerable number of these palsies in patients suffering from Graves's disease. He had no satisfactory explanation of the fact to offer, and one of the difficulties in determining the nature of ocular palsies was the paucity of careful histological work. In a considerable proportion of the cases of Graves's disease with ocular palsy there was but little proptosis, though he admitted that in some the muscular weakness was due to mechanical conditions. Wilbrand and Sänger stated that the ocular palsies in Graves's disease were usually due to nuclear degenerations. With regard to so-called rheumatic or toxic neuritis of oculo-motor nerves, he had seen a number of these cases, and there was a frequent involvement of the external rectus or of the muscles innervated by the third nerve, associated with pain in the forehead on the same side; sometimes there was considerable anæsthesia. In some of the cases of the kind he had encountered there was a septic focus in the vicinity. It was not yet known what a rheumatic neuritis was. Déjerine and others had found merely degenerative changes in some part of the nerve. It would be difficult to conceive of exposure to cold involving ocular nerves in their intracranial course. He did not feel that these cases were rheumatic nor purely toxic, because most toxic affections were bilateral, or at least more or less symmetrical, whereas most of the palsies were unilateral, or certainly asymmetrical. In the spinal cord local collections of cerebro-spinal fluid formed and compressed the roots of the nerves or the cord itself; similarly he thought loculated collections *of* cerebro-spinal fluid might form in the base of the brain and there involve one of the oculo-motor nerves. He had seen cases of chronic nuclear palsy. One had weakness and limitation of eye movements in all directions, with bilateral ptosis. The intrinsic muscles were intact. The ocular palsy in this case was associated with wasting of certain other groups of muscles, especially *those* at the shoulder girdle, of the progressive muscular atrophy type.

Complex Problems of Ætiology.

Mr. **LESLIE PATON** spoke of the complexity of the subject. One disease alone, such as syphilis, could produce oculo-motor paralysis in numberless ways.

It might affect any part of the oculo-motor apparatus—cortical, supranuclear, nuclear, nerve roots, nerve trunks in their intracranial course, in the cavernous sinus, in the orbit, or it might affect the muscles themselves. Syphilis could set up disease of the vessels, and hæmorrhages might occur affecting the nuclei or the nerve roots; or a syphilitic arteritis in the internal carotid might press on nerve trunks in the wall of the cavernous sinus. Similarly an endarteritis might affect the vessels supplying the crura, the mid-brain, or the pons, and produce areas of softening. Or syphilis might give rise to tabes or general paralysis and to the variety of ocular disturbances arising in these diseases. Yet probably not more than 40 per cent. of cases of ophthalmoplegia were due to syphilis. Oculo-motor paralyses were divisible into three main groups: (1) Paralyses of central or cerebral origin. Subgroups of these were supranuclear lesions, internuclear lesions, nuclear, and nerve root lesions. (2) Paralyses of extra-cerebral origin—i.e., of nerve trunks, including intracranial and intraorbital cases. (3) Paralyses of muscular origin. He said the important internuclear set of fibres was in the posterior longitudinal bundle; it was by means of this bundle that the various oculo-motor nuclei were brought into connexion with each other and with the vestibular and auditory functions, also with the general, the muscular, the sense, and other afferent impulses in the body. The most important nucleus of origin of these fibres lay in Dieter's nucleus. The control of the internal musculature of the eye was a matter of considerable doubt. The vascular supply of the oculo-motor nuclei was derived from the anterior end of the basilar artery. Nuclear ophthalmoplegias, or ophthalmoplegias proper, could be subdivided into acute and chronic types. The first included the toxic form caused by alcohol. Wernicke's acute polio-encephalitis superior hæmorrhagica was the best example. Good examples of the infective type of acute ophthalmoplegia were found in lethargic encephalitis, influenza, and syphilis. But in some cases no infective agent could be found. The most important form of chronic progressive ophthalmoplegia was that occurring in tabes and general paralysis of the insane. Some ophthalmoplegias were of congenital origin, others were of a distinct familial type.

Rheumatic and other Toxi-infective Origin.

Dr. **WILFRED HARRIS** considered that cases of chronic nervous disease in which there was weakness of one internal rectus in lateral conjugate deviation were not very rare. He had seen the sixth nerve suffer after the injection of the Gasserian ganglion with alcohol. Recovery ensued after about four months. He asked for opinions as to the existence of rheumatic neuritis of the oculo-motor branches of the third or sixth nerve in the orbit. He described cases in which the symptoms seemed very suggestive of rheumatism as the cause.

Mr. **GRAY CLEGG** (Manchester) spoke of ophthalmoplegia in Graves's disease. He said that Osler and Macrae regarded the paralyses of ocular muscles occurring in Graves's disease as complications, rather than as part of the main disease. One authority, Suker, said a new ocular muscle symptom was present in a number of cases of Graves's disease—namely, "deficient complementary fixation in lateral eye rotations," he regarding it as due to a dissociation in the functions of the sympathetic and the extra oculomotor nerves of the eye.

Dr. **KINNIER WILSON** discussed the question of a possible unilateral cranial polyneuritis, which he regarded as one of considerable clinical importance. He described the case of a man severely ill with a general pneumococcal infection, showing itself as pleurisy and pneumonia, and who had complete paralysis of the seventh, eighth, ninth, tenth, eleventh, and twelfth cranial nerves, but on the right side only. There was no involvement of an ocular muscle or ocular nerve in that particular case, but he had seen analogous cases in which the sixth and seventh or the fifth, sixth, and seventh were involved, and saw no reason to doubt their toxi-infective origin.

Mr. **N. BISHOP HARMAN** remarked on the comparative rarity of the kind of cases now under discussion. In a consecutive series of 5000 cases he found only 27 instances of ocular palsy—17 males, 10 females. Seven were due to injury, five to syphilis, five to general vascular disease or degeneration. Two cases in which the palsy followed exposure might be disputed by the neurologists, but in one of them there were clear manifestations of inflammation over the affected muscle, and both cleared up rapidly. Mr. Harman agreed that, apart from the cases of paralysis due to direct injury to the bones of the orbit and those ensuing on exposure, the occurrence of such a paralysis was a sign of serious general disease, but his own cases did not encourage the view that life was shortened thereby. He gave a careful analysis of his 27 cases. Discussing the treatment, he advocated countering the danger of diplopia by the wearing of one lens of ground glass. When the

lesion was peripheral he found blisters, faradism, and massage were effective local measures.

Progressive External Ophthalmoplegia.

Mr. M. L. HINE read a contribution by Mr. W. H. MCMULLEN and himself on Chronic Progressive Ophthalmoplegia Externa. Wilbrand and Sänger, in their text-book, grouped as a clinical entity certain cases of external ophthalmoplegia which they considered as having certain definite characteristics to distinguish them from the congenital cases of this affection and from those due to a defined toxic cause or to syphilis, or associated with manifestations of wider-spread disease of the nervous system. It was, however, by no means generally agreed that a separate classification of these was justified. The characteristics associated with them Wilbrand and Sänger gave as: (1) onset gradual, usually in infancy; (2) it is bilateral and very slowly progressive; (3) no other signs of nervous disorder or impaired health; (4) it might come to a standstill at any stage, but generally ended in complete external ophthalmoplegia.—Mr. HINE and Mr. MCMULLEN showed three patients whose condition illustrated their thesis.

Mr. M. S. MAYOU sent a brief description of two cases of paresis of the upward and downward movements of the eyes. The first definitely followed straining at stool. The pupils were active to light and lateral movement was unimpaired; he could converge. Vision was 6/12 in each eye, there was no optic neuritis, and the knee-jerks were present. Downward movement first improved, attempts at upward movement causing a coarse nystagmus. Wassermann was negative. Recovery was now practically complete. The second patient was suddenly seized with intense vertigo and diplopia. Vision was 6/6 in either eye, but the pupils were very sluggish, and he had no power of convergence. Wassermann was negative, knee-jerks present. No other nerve affection could be discovered. Both cases improved on iodide of potassium. In previously recorded cases the position of the lesion had been variously stated to be the optic thalamus, corpora quadrigemina, pons, and subcortical, but there seemed to have been no verification of this by autopsy.

Sixth Nerve Paralysis.

Mr. J. H. FISHER, referring to the suggestion that alcohol injections into the Gasserian ganglion sometimes caused sixth nerve paralysis, owing to damage of the nerve in the floor of the cavernous sinus, said he thought that was a rather improbable situation for such an event to take place. He knew of one case of sixth nerve paralysis in which the lesion was not there. The lesion in the cases referred to was not, he thought, in the cavernous sinus, but posterior to it.

Dr. TAYLOR said he had always felt somewhat sceptical about paralysis of ocular muscles being of so-called rheumatic origin. Seventh nerve paralysis was very common as a result of so-called rheumatic neuritis, but he had for years watched cases of ordinary seventh nerve paralysis without ever seeing sixth nerve paralysis associated with it. He had hoped to hear more allusion to cases of myasthenia gravis, as that was one of the common grounds on which neurologists and ophthalmologists met. A number of these cases had been referred to him by his colleagues at Moorfields. One of the most astonishing features about them was the great variability in their course, though some progressed steadily downwards. He referred also to a peculiar case in which a man with ocular palsies, double ptosis, &c., but with very little defect in limb movements, in whom the palsies were progressing downwards, so that later he could neither get about nor feed himself, developed an intense desire to return to his home in Hampshire. He went, and the next that was heard of him was in a letter written by himself, asking that the military authorities should be informed that he was not fit for service, as he had had myasthenia gravis.

The openers replied.

During the meeting Mr. J. H. Parsons was congratulated from the chair on his nomination for the Fellowship of the Royal Society.

SECTION OF ANÆSTHETICS.

AT a meeting of this section of the Royal Society of Medicine held on March 5th Dr. H. J. SHIRLEY, the President, in the chair, Dr. W. J. MCCARDIE read a paper on

Explosion of Ether Vapour During Laryngoscopy.

It occurred in a man of 56, who was given open ether to induce anæsthesia for laryngoscopy and removal of a piece of the vocal cord. For some minutes before the laryngoscope was introduced ether with oxygen was given through a nasal catheter in addition to ether from the mask. The mouth being opened, ether and oxygen still passing in through the nose, Mr. Musgrave Woodman began to introduce Hill's electric laryngoscope. It had not entered more than an inch when there were heard two or three loud reports like small pistol-shots, and flames issued from the patient's mouth. These were 5 or 6 inches high, and like those seen if a Winchester quart bottle of ether is set on fire. The nasal tube was at once pulled out and the flames quickly died. Anæsthesia was continued with chloroform and oxygen without trouble. There was no obvious burning, merely reddening of the mouth and pharynx, and the patient recovered normally and had no after cough. At the time of the explosion the room (temp. 65° F.) was lighted by two ½ watt bulbs and one Osram bulb under a shade 2½ feet away almost directly over the patient's head. The bulb of the laryngoscope light did not fuse, and the light appeared in order and there was no evidence of short-circuiting. No heat could be felt by the hand when the light was first switched on. The warm room, warm mouth, warm electric light, warm ether and oxygen, would all help towards the explosion. Ether vapour would take fire at a considerable distance from the source of heat. Dr. Squibb had related that he had seen ether take fire at a measured distance of 15 feet between the source of escaping vapour and the source of fire. Considering the absolute coincidence of the explosion with the introduction of the lamp, the cause must be found in the electric bulb of the laryngoscope.

Dr. McCardie related the only other recorded case of ignition of ether vapour in the presence of a closed electric light. Other instances of ether vapour ignition were brought forward by members of the section.

Mr. RAYMOND APPERLY read a paper on

The Importance of an Examination of Patients by the Anæsthetist Previous to the Administration of Anæsthetics.

The speaker pointed out that improvements in anæsthesia during the last 15 years had been not in the increased number of drugs at our disposal but in the variety of more scientific methods of administering them. This placed on the anæsthetist an increased responsibility in his choice of method. There was still room for improvement both in diminishing fatalities and in reducing after-effects, and one step towards this lay in thorough examination of patients some time before operation. The condition of the cardio-vascular, respiratory, and nervous systems could only be ascertained in this way, as well as the efficiency or otherwise of the kidneys. Previous examination too gave the anæsthetist time to think out the line of action best suited to the individual. Moreover, cumbersome or elaborate apparatus might be required, which would not be present unless the need for it had been appreciated beforehand. The examination was an advantage to the patient, who felt that nothing was being left to chance, to the anæsthetist who might glean important facts for his guidance, and to the surgeon who was able to rely on the anæsthetist's opinion as to the patient's ability to stand a prolonged operation. The physician, who seldom saw an operation, was not so well qualified a guide. The risks which a patient ran were not confined to serious operations. For minor ones they were often grave just because of the slightness of the operation leading to neglect of necessary precautions regarding the anæsthetic. In private practice patents in nursing homes were at hand and could be seen on the day before operation. In hospital practice there was routine examination by house officers and the anæsthetist was supplied with the information acquired. One class of patient, that which was admitted to the cancer department of the Middlesex Hospital, had especially emphasised for us the importance of preliminary examination. Mr. Apperly said that cachectic debilitated persons, often with secondary

ROYAL SOCIETY OF MEDICINE.

SECTIONS OF NEUROLOGY AND OPHTHALMOLOGY.

OCULAR PALSIES.

Two evenings were set apart by these sections of the Royal Society of Medicine for a discussion on Ocular Palsies, at which the chair was occupied alternatively by Professor E. S. Reynolds and Dr. James Taylor.

Dr. Gordon Holmes opened the debate by a reasoned dissertation on the various forms of palsy met with in eye muscles and the anatomical situation of the causal lesions.

He recommended a careful study of the normal movements of the eyeball, and set out the associated palsies of the muscles which normally act together. An interesting point was the "unwillingness" of a patient with cerebellar disease to turn the eyes to the side of the lesion in performing conjugate deviation, which was met with in some cases of this disease, an important and new observation. Since he had been attached to the Moorfields Eye Hospital he had seen many cases of ocular palsy, and he was always conscious of difficulty in deciding what any case was likely to be due to. Only by a careful weighing of signs of associated disease could a presumptive diagnosis be arrived at. With regard to Graves's disease it was surprising to remember that not many years ago Dr. Hughlings Jackson and others regarded ocular palsies in association with Graves's disease as very exceptional. At Moorfields he (the speaker) saw a considerable number of these palsies in patients suffering from Graves's disease. He had no satisfactory explanation of the fact to offer, and one of the difficulties in determining the nature of ocular palsies was the paucity of careful histological work. In a considerable proportion of the cases of Graves's disease with ocular palsy there was but little proptosis, though he admitted that in some the muscular weakness was due to mechanical conditions. Wilbrand and Sänger stated that the ocular palsies in Graves's disease were usually due to nuclear degenerations. With regard to so-called rheumatic or toxic neuritis of oculo-motor nerves, he had seen a number of these cases, and there was a frequent involvement of the external rectus or of the muscles innervated by the third nerve, associated with pain in the forehead on the same side; sometimes there was considerable anæsthesia. In some of the cases of the kind he had encountered there was a septic focus in the vicinity. It was not yet known what a rheumatic neuritis was. Déjerine and others had found merely degenerative changes in some part of the nerve. It would be difficult to conceive of exposure to cold involving ocular nerves in their intracranial course. He did not feel that these cases were rheumatic nor purely toxic, because most toxic affections were bilateral, or at least more or less symmetrical, whereas most of the palsies were unilateral, or certainly asymmetrical. In the spinal cord local collections of cerebro-spinal fluid formed and compressed the roots of the nerves or the cord itself; similarly he thought loculated collections of cerebro-spinal fluid might form in the base of the brain and there involve one of the oculo-motor nerves. He had seen cases of chronic nuclear palsy. One had weakness and limitation of eye movements in all directions, with bilateral ptosis. The intrinsic muscles were intact. The ocular palsy in this case was associated with wasting of certain other groups of muscles, especially those at the shoulder girdle, of the progressive muscular atrophy type.

Complex Problems of Ætiology.

Mr. Leslie Paton spoke of the complexity of the subject. One disease alone, such as syphilis, could produce oculo-motor paralysis in numberless ways.

It might affect any part of the oculo-motor apparatus—cortical, supranuclear, nuclear, nerve roots, nerve trunks in their intracranial course, in the cavernous sinus, in the orbit, or it might affect the muscles themselves. Syphilis could set up disease of the vessels, and hæmorrhages might occur affecting the nuclei or the nerve roots; or a syphilitic arteritis in the internal carotid might press on nerve trunks in the wall of the cavernous sinus. Similarly an endarteritis might affect the vessels supplying the crura, the mid-brain, or the pons, and produce areas of softening. Or syphilis might give rise to tabes or general paralysis and to the variety of ocular disturbances arising in these diseases. Yet probably not more than 40 per cent. of cases of ophthalmoplegia were due to syphilis. Oculo-motor paralyses were divisible into three main groups: (1) Paralyses of central or cerebral origin. Subgroups of these were supranuclear lesions, internuclear lesions, nuclear, and nerve root lesions. (2) Paralyses of extra-cerebral origin—i.e., of nerve trunks, including intracranial and intraorbital cases. (3) Paralyses of muscular origin. He said the important internucleal set of fibres was in the posterior longitudinal bundle; it was by means of this bundle that the various oculo-motor nuclei were brought into connexion with each other and with the vestibular and auditory functions, also with the general, the muscular, the sense, and other afferent impulses in the body. The most important nucleus of origin of these fibres lay in Dieter's nucleus. The control of the internal musculature of the eye was a matter of considerable doubt. The vascular supply of the oculo-motor nuclei was derived from the anterior end of the basilar artery. Nuclear ophthalmoplegias, or ophthalmoplegias proper, could be subdivided into acute and chronic types. The first included the toxic form caused by alcohol. Wernicke's acute polio-encephalitis superior hæmorrhagica was the best example. Good examples of the infective type of acute ophthalmoplegia were found in lethargic encephalitis, influenza, and syphilis. But in some cases no infective agent could be found. The most important form of chronic progressive ophthalmoplegia was that occurring in tabes and general paralysis of the insane. Some ophthalmoplegias were of congenital origin, others were of a distinct familial type.

Rheumatic and other Toxi-infective Origin.

Dr. Wilfred Harris considered that cases of chronic nervous disease in which there was weakness of one internal rectus in lateral conjugate deviation were not very rare. He had seen the sixth nerve suffer after the injection of the Gasserian ganglion with alcohol. Recovery ensued after about four months. He asked for opinions as to the existence of rheumatic neuritis of the oculo-motor branches of the third or sixth nerve in the orbit. He described cases in which the symptoms seemed very suggestive of rheumatism as the cause.

Mr. Gray Clegg (Manchester) spoke of ophthalmoplegia in Graves's disease. He said that Osler and Macrae regarded the paralyses of ocular muscles occurring in Graves's disease as complications, rather than as part of the main disease. One authority, Suker, said a new ocular muscle symptom was present in a number of cases of Graves's disease—namely, "deficient complementary fixation in lateral eye rotations," he regarding it as due to a dissociation in the functions of the sympathetic and the extra oculomotor nerves of the eye.

Dr. Kinnier Wilson discussed the question of a possible unilateral cranial polyneuritis, which he regarded as one of considerable clinical importance. He described the case of a man severely ill with a general pneumococcal infection, showing itself as pleurisy and pneumonia, and who had complete paralysis of the seventh, eighth, ninth, tenth, eleventh, and twelfth cranial nerves, but on the right side only. There was no involvement of an ocular muscle or ocular nerve in that particular case, but he had seen analogous cases in which the sixth and seventh or the fifth, sixth, and seventh were involved, and saw no reason to doubt their toxi-infective origin.

Mr. N. Bishop Harman remarked on the comparative rarity of the kind of cases now under discussion. In a consecutive series of 5000 cases he found only 27 instances of ocular palsy—17 males, 10 females. Seven were due to injury, five to syphilis, five to general vascular disease or degeneration. Two cases in which the palsy followed exposure might be disputed by the neurologists, but in one of them there were clear manifestations of inflammation over the affected muscle, and both cleared up rapidly. Mr. Harman agreed that, apart from the cases of paralysis due to direct injury to the bones of the orbit and those ensuing on exposure, the occurrence of such a paralysis was a sign of serious general disease, but his own cases did not encourage the view that life was shortened thereby. He gave a careful analysis of his 27 cases. Discussing the treatment, he advocated countering the danger of diplopia by the wearing of one lens of ground glass. When the

lesion was peripheral he found blisters, faradism, and massage were effective local measures.

Progressive External Ophthalmoplegia.

Mr. M. L. HINE read a contribution by Mr. W. H. MCMULLEN and himself on Chronic Progressive Ophthalmoplegia Externa. Wilbrand and Sänger, in their textbook, grouped as a clinical entity certain cases of external ophthalmoplegia which they considered as having certain definite characteristics to distinguish them from the congenital cases of this affection and from those due to a defined toxic cause or to syphilis, or associated with manifestations of wider-spread disease of the nervous system. It was, however, by no means generally agreed that a separate classification of these was justified. The characteristics associated with them Wilbrand and Sänger gave as: (1) onset gradual, usually in infancy; (2) it is bilateral and very slowly progressive; (3) no other signs of nervous disorder or impaired health; (4) it might come to a standstill at any stage, but generally ended in complete external ophthalmoplegia.—Mr. HINE and Mr. MCMULLEN showed three patients whose condition illustrated their thesis.

Mr. M. S. MAYOU sent a brief description of two cases of paresis of the upward and downward movements of the eyes. The first definitely followed straining at stool. The pupils were active to light and lateral movement was unimpaired; he could converge. Vision was 6/12 in each eye, there was no optic neuritis, and the knee-jerks were present. Downward movement first improved, attempts at upward movement causing a coarse nystagmus. Wassermann was negative. Recovery was now practically complete. The second patient was suddenly seized with intense vertigo and diplopia. Vision was 6/6 in either eye, but the pupils were very sluggish, and he had no power of convergence. Wassermann was negative, knee-jerks present. No other nerve affection could be discovered. Both cases improved on iodide of potassium. In previously recorded cases the position of the lesion had been variously stated to be the optic thalamus, corpora quadrigemina, pons, and subcortical, but there seemed to have been no verification of this by autopsy.

Sixth Nerve Paralysis.

Mr. J. H. FISHER, referring to the suggestion that alcohol injections into the Gasserian ganglion sometimes caused sixth nerve paralysis, owing to damage of the nerve in the floor of the cavernous sinus, said he thought that was a rather improbable situation for such an event to take place. He knew of one case of sixth nerve paralysis in which the lesion was not there. The lesion in the cases referred to was not, he thought, in the cavernous sinus, but posterior to it.

Dr. TAYLOR said he had always felt somewhat sceptical about paralysis of ocular muscles being of so-called rheumatic origin. Dr. McCardie related the only other recorded case of ignition of ether vapour in the presence of a closed electric light. Other instances of ether vapour ignition were brought forward by members of the section.

Mr. RAYMOND APPERLY read a paper on

The Importance of an Examination of Patients by the Anæsthetist Previous to the Administration of Anæsthetics.

The speaker pointed out that improvements in anæsthesia during the last 15 years had been not in the increased number of drugs at our disposal but in the variety of more scientific methods of administering them. This placed on the anæsthetist an increased responsibility in his choice of method. There was still room for improvement both in diminishing fatalities and in reducing after-effects, and one step towards this lay in thorough examination of patients some time before operation. The condition of the cardio-vascular, respiratory, and nervous systems could only be ascertained in this way, as well as the efficiency or otherwise of the kidneys. Previous examination too gave the anæsthetist time to think out the line of action best suited to the individual. Moreover, cumbersome or elaborate apparatus might be required, which would not be present unless the need for it had been appreciated beforehand. The examination was an advantage to the patient, who felt that nothing was being left to chance, to the anæsthetist who might glean important facts for his guidance, and to the surgeon who was able to rely on the anæsthetist's opinion as to the patient's ability to stand a prolonged operation. The physician, who seldom saw an operation, was not so well qualified a guide. The risks which a patient ran were not confined to serious operations. For minor ones they were often grave just because of the slightness of the operation leading to neglect of necessary precautions regarding the anæsthetic. In private practice patents in nursing homes were at hand and could be seen on the day before operation. In hospital practice there was routine examination by house officers and the anæsthetist was supplied with the information acquired. One class of patient, that which was admitted to the cancer department of the Middlesex Hospital, had especially emphasised for us the importance of preliminary examination. Mr. Apperly said that cachectic debilitated persons, often with secondary

growths in mediastinum or pleura and obstructed air-passages, make one extremely cautious in examination before deciding to give an anæsthetic. He related cases illustrative of his argument.

The Purification of Anæsthetics: A New Preparation.

At a meeting held on April 1st Dr. R. L. MACKENZIE WALLIS and Mr. C. LANGTON HEWER read a paper entitled "A New General Anæsthetic, its Theory and Practice." The first part of the paper, dealing with the theory upon which the anæsthetic was based, was given by Dr. Mackenzie Wallis. The development of the subject was given in detail and the various steps which led up to the final stage in production. The speaker referred to his work on the impurities in anæsthetics, especially those which exist in a preformed state. The impurities which develop as a result of oxidation on standing were also described. One of the chief and most objectionable impurities in anæsthetics appeared to be the mercaptans and other organic compounds containing sulphur. The removal of these compounds was beset with many difficulties, but was ultimately overcome by the use of finely divided permanganate. This reagent absorbs the mercaptans from ether, and after distillation the distillate is found to be free from them. It was soon found, however, that such highly purified ether had lost its anæsthetic properties. The gases carbon dioxide and ethylene as devised by Dr. Cotton in America were passed into this ether, but still the desired result was not obtained. After a laborious and concentrated search it was found that the higher ketones were responsible for the anæsthetic action, and for the retention of the gases in the ether. As a result of these experiments the preparation of an anæsthetic was devised. On account of the quantity available, and also from the question of cost, pure ether was used as the vehicle. This pure ether could be made quite easily from ordinary methylated ether by means of permanganate and anhydrous copper sulphate. Into this pure ether, which possessed no anæsthetic properties, the gases carbon dioxide and ethylene were introduced along with the ketones. The exact ketone, or combination of ketones could not be determined, but this phase of the subject is now being pursued. The resulting product has a slightly sweet smell, and is practically odourless. It appears to keep better than ordinary ether, or even pure ether. The carbon dioxide in the ether appears to exert a stabilising action and is material in that it assists in the formation of the anæsthetic complex. It is possible that any non-volatile solvent may be used, but pure ether appears to be the best vehicle so far discovered. The anæsthetic prepared in this way has been tried on a large number of cases by Mr. Langton Hewer, and all of this was made by the speaker. It was, however, found to be impossible to cope with the demand, and so recently its manufacture has been taken up by a well-known chemical firm, and they have given their preparation the name of "Ethanesal."

The results of the application of this anæsthetic in surgery were given in the second part of this paper by Mr. Langton Hewer.

SECTION OF OTOLOGY.

A MEETING of this section of the Royal Society of Medicine was held on March 18th. Sir CHARLES BALLANCE, President of the section, being in the chair.

Pathological Demonstration.

Dr. ALBERT GRAY (Glasgow) gave, by means of the epidiascope, a minute demonstration of the conditions found in two cases of acute septic meningitis, contrasting the appearances with those found in the chronic disease.—The PRESIDENT expressed the gratitude of the section for the exhibit, and members discussed the path of infection.

Ears Under Modern War Conditions.

Papers on this subject were read by Mr. JEFFERSON FAULDER and Mr. LIONEL COLLEDGE, both based upon their experiences near the front line during the war.

Mr. FAULDER said that, especially in the excitement of the early days of the war, the examination of ears was not made easy by the conditions under which the recruiting medical officers did their work, and only high degrees of deafness or gross disease appeared on the medical history sheets. Contrary to expectation, the degree of concussion caused by firing a gun did not bear a direct relation to the gun's calibre. It was necessary to draw a distinction between the effects of the firing of these weapons and the effects of the explosion of their projectiles; the former was a complex process, whereas the effect of the latter was intensely disruptive and had a cumulative result on the ear. During 20 years' service with artillery he had never seen an ear-drum ruptured by the firing of a gun, except when the gunner inadvertently got too near the muzzle. He had seen many cases of hæmorrhage (in most cases slight) from the ears. Trauma of the drum should not be diagnosed solely on the presence of blood in the meatus. Men with damaged ears, which had left cicatrices, were found to have suffered less from war conditions than did those with normal ears. The men, as a rule, objected to plugs in the ears; he used nothing beyond wool moistened with paraffin or glycerine. A common phenomenon observed during the war was hyperæsthesia (as distinct from psychological nervousness), so that after a time the ordinary sounds and noises of life became painful. This appeared to have no relation to the presence of actual deafness. During the recent war he had seen only three certain cases of rupture of the drum; two of the men had other injuries also. In all three the drum was torn into strips, and in one no malleus could be seen. Deafness, nystagmus, and tinnitus were present in all when investigation could be made, and two had a staggering gait; the injuries of the third prevented walking. He discussed the condensation and rarefaction pressure agencies in the production of actual tympanic rupture by explosions.

Mr. COLLEDGE said his observations were made from a less perilous position. Of 456 ear cases he saw, 66 were in gunners. He divided his cases into (1) those in whom the deafness was progressive through continual gun-fire; (2) cases in which the condition followed proximity to one explosion. Those in the second class recovered much the more rapidly; in some of these the membrane was dotted over by punctate hæmorrhages. Genuine primary rupture of the normal tympanic membrance was not very common; many cases diagnosed as such were instances of old perforation. In cases of simple torn membrane the prognosis was good. Actual malingering was uncommon in regard to deafness during the war, but he had some clear instances, and he detailed the tests by which deception was discovered.

Device for Tuning-fork Testing.

Mr. E. A. PETERS and Mr. R. LAKE exhibited a device for attachment to tuning-forks when testing bone-conduction. The greater the pressure on the bone the longer the vibrations of the fork were heard by the patient, and this arrangement ensured the continuance of a certain known pressure. When the pressure was 8 ounces, the fork was heard by the normal person 29 seconds; when it was 16 ounces the sound was heard 8 to 10 seconds longer.

Lateral Sinus Thrombosis without Otorrhœa.

Mr. W. M. MOLLISON showed two cases of this condition. The first was that of a young woman, aged 20, who, three weeks before being seen, had pharyngitis. During the past fortnight she had had left earache and deafness, but no pus had come from the ear. On several occasions the temperature rose to 104° F., but there were no rigors. The left membrane was found to be dull and irregular, and there was tenderness over the mastoid and neck. At the operation granulations were found in the antrum, which led backwards and upwards to the lateral sinus, on the wall of which there was pus. The internal jugular was ligatured. As the temperature continued high a further operation was done two days later, when the sinus was found to be thrombosed 1½ inches further back. The patient recovered. The second case was that of a boy, aged 17, who ten days ago commenced to complain of earache, and the temperature rose until it reached 104° F. Mr. E. W. Sheaf operated and found pus in the mastoid. As the temperature still remained high and the boy looked very ill the wound was reopened by Mr. Mollison and the sinus exposed, when an extra-dural abscess was discovered. Treatment of this brought about recovery.

Mr. G. W. DAWSON and Mr. SYDNEY SCOTT related similar cases in their own practice. Mr. Scott thought such cases occurred oftener than was generally supposed. The discussion was also carried on by Sir WILLIAM MILLIGAN, Mr. E. M. WOODMAN, Mr. W. STUART-LOW, and others. The PRESIDENT referred to cases which healed in one direction and extended in the other. Mr. F. J. CLEMINSON referred to the case of a boy who came with fluctuating disease over the right mastoid, but who had good hearing and a perfect drum. An abscess was found at the operation leading down to a fistula over the lateral sinus. The sinus and the remainder of the mastoid process were healthy. Culture tests were negative. He considered it must have been a localised tuberculous osteomyelitis.

SECTION OF LARYNGOLOGY.

EXHIBITION OF CASES AND SPECIMENS.

A MEETING of this section of the Royal Society of Medicine was held on April 1st, Dr. W. JOBSON HORNE, the President, being in the chair.

A Case of Pharyngeal Pouch in 1760.

Mr. ARCHER RYLAND showed, by means of the epidiascope, illustrations of a case of pharyngeal pouch which was investigated and reported upon 160 years ago. The case was fully and frankly reported, and was followed through to the post-mortem room. There was a definite association with the lodgment of a foreign body: the patient swallowed a cherry stone. The pouch appeared to have originated from the lower part of the pharynx, opposite the cricoid. The authors of the description seemed to have satisfied themselves that the whole thickness of the pharyngeal wall was represented in the wall of the pouch. The man, aged 60, was unable to pass food into the stomach. Five years before the acute difficulty he had swallowed a cherry stone, which had remained in the pharynx three days before being coughed up. The proportion of a meal which was injected became gradually larger. The use successively of a probang, a bullet strung on silk, catheters, &c., having failed, half a pound of quicksilver was given in one quantity. Death occurred 13 days after the first attempt. At the autopsy there was found a considerable muscular bag between the œsophagus and the vertebræ, and it was thought that during the three days of its retention the cherry stone must have been forced in between the irregular folds which abound in the lower part of the pharynx, and the food taken thereafter was forced into the cavity so formed. It was afterwards agreed that nothing worse than the quicksilver could have been used.

Dr. WILLIAM HILL doubted whether the pouching included all the structures of the pharyngeal wall; neither did he feel convinced that the diverticulum was a direct result of swallowing the cherry stone and getting an impaction. Probably the stricture existed before, and as it became smaller it succeeded in holding a foreign body up, so that the foreign body was only an incident in the case.—Lieutenant-Colonel MYERS narrated a case in which the frequent passage of a stomach-tube to carry out lavage resulted in the formation of an œsophageal pouch. The present state of affairs was that two-thirds of each meal was ejected.

Lateral Nasal Proboscis.

Mr. PHILIP FRANKLIN showed a case of this condition in a male child, and exhibited by the epidiascope, illustrations of cyclops and demicyclops. Demicyclops was due to an early fusion of the maxillary process to the exclusion of the mesial and lateral nasal processes of the affected side. This accounted for the absence of a premaxillary bone, which developed from the mesial nasal process. In true cyclops, he said, the orbital and nasal cavities, the eye and the optic nerve were fused into one. The eye of this child should be removed with the appendage, so as to avoid a fistula, and obviate lacrymation. In three cases examined there was no trace of the olfactory nerve. He expressed his intention of having an examination made of the secretion from the proboscis.

Large Dental Cyst.—Retention Cyst of Nostril Floor.

Mr. G. W. DAWSON showed a woman, aged 44, who for 25 years had had a painless hard swelling in the left cheek; she also had local neuritis and occipital pain. When seen the floor of the left nostril was bulged upwards, and that side was dark on transillumination. A cyst was found full of thick purulent matter. Its entire outer wall was removed.—Mr. W. STUART-LOW discouraged packing and syringing the cavity, and recommended swabbing with chloride of zinc of increasing strength.—Dr. DAN MCKENZIE referred to the plan of closing such a cavity by a plastic flap taken from the inner surface of the cheek. He suggested the making of a communication between the present cavity and the antrum, so that drainage could be carried on through the nose.

Mr. DAWSON also brought a girl, aged 23, who last year had a retention cyst of the right nostril, which was removed. She now had a similar formation on the floor of the left nostril, and complained of pain on the left side of the head, and aching on the bridge of the nose.

Tumour of Supra-tonsillar Fossa.

Mr. C. W. M. HOPE showed a patient with a tumour growing from the right supra-tonsillar fossa region, which members who spoke on it considered to be a mere overgrowth of the tonsil itself, consisting of ordinary lymphatic tissue. Mr. Hope expressed his intention of removing it with the tonsil.

Scarlatinal Scarring of Pharynx.

Dr. DAN MCKENZIE exhibited a middle-aged woman whose uvula was shifted on to the right side of the palate by old cicatricial contraction. Wassermann was negative. The condition was probably a sequel of the ulceration, which occurred during acute scarlatina at 5 years of age.

Bilateral Abductor Paresis of Vocal Cords.

Mr. M. VLASTO showed a man, aged 64, with this condition. He had had hoarseness and difficulty of breathing 20 years. Wassermann had been positive, and in 1916 he had a course of injections. He was now worse, and had breathlessness on exertion and inspiratory stridor.—Sir STCLAIR THOMSON regarded the case as one of syphilitic peripheral neuritis, but said that in 20 to 30 per cent. of the published cases the cause of the paralysis could not be definitely determined. He advised prompt tracheotomy owing to the danger of sudden death due to back pressure on her heart. He related a similar case in which this was the end.—Professor F. HOBDAY, speaking from a large veterinary experience, advocated the ventricle-stripping operation for such cases in the human subject, as he had done many times on horses which were afflicted with "roaring." Instead of doing tracheotomy, the lining membrane of the ventricle was stripped behind the paralysed vocal cord. The result in the horse was a permanent success. He quoted cases.

Sore-throat, with Excessive Mucous Secretion.

Mr. JEFFERSON FAULDER showed a man, aged 64, who for the last 12 months had had a sore-throat and excessive secretion of mucus, with an alteration in his voice. Dyspnœa was at times severe, but he had no dysphagia. Wassermann was negative. On the right half of the larynx there was an irregular growth, which might be intrinsic cancer advancing towards the hypopharynx. This view Mr. J. F. O'MALLEY expressed his agreement with. Sir JAMES DUNDAS-GRANT, however, in the absence of pain on swallowing, did not think it was malignant, especially as the voice was well preserved. Sir STCLAIR THOMSON did not regard it as cancerous, and said the case reminded him of one of fatty tumour. He counselled removal by the direct method and a microscopical examination. The PRESIDENT thought the free movement of the cord and the lack of evidence of infiltration were against the condition being malignant.

SOCIETY OF MEDICAL OFFICERS OF HEALTH:

TUBERCULOSIS GROUP.

HOSPITAL TREATMENT OF ACUTE AND ADVANCED PULMONARY TUBERCULOSIS.

AN ordinary general meeting of this group was held at the house of the society, 1, Upper Montague-street, W.C., on April 1st, Dr. **HENRY A. ELLIS** in the chair, when a paper was delivered by Dr. **H. HYSLOP THOMSON**, M.O.H., county of Hertford, on this subject.

Dr. Thomson said: The question of the treatment of tuberculosis may be regarded from two points of view—that of the soil and that of the seed. Hospital treatment has for its aim to eliminate the bacillus. One cannot but be impressed with the limitations of our knowledge with respect to tuberculosis, and reference must be made to certain questions regarding the ætiology of the disease, since the chief aim of hospital treatment is to secure the segregation of those individuals who are expelling the bacilli in vast numbers.

The Origin of the Bacillus.

Whence does the bacillus come? Two sources of origin have been discussed—(1) the bacillus is derived from a pre-existing case of the disease, or (2) it may arise by *transmutation from some non-pathogenic type* of organism. There are those who hold that evolution may be at work with the tubercle bacillus as with other forms of life, subjecting it to the influence of the forces of natural selection and the survival of the fittest, that we only know it in its parasitic phase and that the disease is practically unknown in natural conditions of life. The bearing of the problem on the question of hospital treatment is that if the chief source of origin of the bacillus is the sputum from a case of the disease, then the provision of adequate hospital accommodation will lead in time to its elimination as a pathogenic organism, whereas if the supply be renewed by transmutation of a non-pathogenic organism, then unless the conditions which give rise to this transformation are modified or changed, elimination will become impossible. The disappearance of leprosy in the Middle Ages was due not only to the provision of adequate accommodation for the patients, but also to the fact that altered conditions of living led to modifications in the virulence of the organism which caused the disease.

Fourfold Aims of Hospital Treatment.

Too much attention has been paid in the past to institutional treatment of tuberculosis other than hospital, which should form the foundation of all treatment. Its aims are fourfold: to secure the segregation of advanced cases; provide conservative and curative measures; provide facilities for the diagnosis of doubtful cases and measures of relief for the hopelessly diseased. Segregation in advanced cases is necessary because, owing to increasing weakness, the patient becomes unable to expel his sputum properly and is liable for that reason to contaminate his clothes and other things. Koch himself expressed the opinion that the fall in the death-rate from tuberculosis in England was due largely to the provision made in infirmaries for the segregation of the advanced cases of the disease. But many cases of tuberculosis begin with acute symptoms when the most important thing required is rest in bed, and this can only be carried out satisfactorily in a well-equipped hospital, as also certain specific methods of treatment—e.g., artificial pneumothorax. A number of beds should be set aside for observation cases, since there are numerous instances of patients who have been diagnosed as suffering from tuberculosis in whom the diagnosis has not been confirmed. It is unfortunate that the line of least resistance is for the tuberculosis officer to make a positive diagnosis. Palliative treatment of advanced cases can be much more efficiently carried out in hospital than at home under unsatisfactory and often unhygienic conditions. Borderland cases and those where there is doubt as to the best method of treatment should be admitted to hospital for observation. Perhaps the most difficult cases of all to deal with would be those of the advanced ambulant type, who are unable to work, and, if admitted to hospital for an indefinite period, would make heavy demands on the available accommodation. This difficulty might, at least partially, be got over by admitting them for short terms at intervals. Treatment, however provided, must be efficient, economical, and have regard to the psychology of the patient.

In addition to the special hospital it has been suggested that a special hospital block should be provided in every sanatorium, and that the patients should be distributed in separate homes, which would be a solution of the question not only unsatisfactory but costly. One or two special institutions, the number varying according to the needs of the population in which they are placed, would be the ideal to aim at, although the problem is not an easy one to solve in regard to small areas. At present the advanced case is refused admittance into a general hospital, but the advanced case is surely entitled to treatment, and this can only be provided in a special institution. No doubt difficulties would arise with regard to the distance to which patients and their friends might have to travel and to the depressing effects which the death of one patient might have on the others, but, whatever the disadvantages, they would be far outweighed by the advantages which would accrue from the best of nursing and attention and treatment. And together with this higher standard of treatment would go economy of structure and administration. Four or five beds to each 1000 of the population would suffice. The lecturer concluded by stating his opinion that rest is the one great essential in the treatment of tuberculosis, and that nowhere can this be more effectively carried out than in a special hospital.

A discussion followed the reading of the paper in which Drs. **H. A. ELLIS**, **C. ROLLESTON**, **CAMPBELL McCLURE**, **G. MACDONALD**, **J. SORLEY**, and others took part, and a very hearty vote of thanks was awarded to Dr. Thomson for his paper.

LIVERPOOL MEDICAL INSTITUTION.

AT a meeting of this society held on March 31st, Mr. **THURSTAN HOLLAND**, Vice-President, in the chair, Mr. **BLAIR BELL** discussed the

Indications for Blood Transfusion,

giving illustrative cases. He divided the conditions for which blood transfusion is required into three main groups, with various subdivisions in each.

Group A contained those cases in which there is loss of all the constituents of the blood from an acute large hæmorrhage, of the solid constituents occurring in chronic limited hæmorrhages, or of much fluid, as in cases of shock.

Group B contained those cases in which there is absent from the blood some constituent present in normal circumstances, or one usually formed in response to specific stimulation. In this group are such conditions as hæmophilia, in which disease operations may safely be performed immediately after blood transfusion. Included also are cases of eclampsia when a chemical antibody to placental toxin is believed to be absent from the blood, and acute and chronic infections in which the patient's own bacterial antibodies are insufficient.

Group C contained those diseases in which there is blood destruction. Although good results were claimed for the treatment by blood transfusion of pernicious anæmia it is probable that the result was only temporary and that transfusion must often be repeated.

Mr. Blair Bell gave a short account of the blood grouping of donors of blood and of the problems which may be connected with the grouping, such as the heteroplastic grafting of tissues and selective sterility. Finally he discussed the various methods of blood transfusion and emphasised the fact that, in his opinion, the citrated blood method is the only generally applicable and safe procedure. He described and demonstrated his own apparatus (a full account of which will be published) whereby the blood of the donors is automatically citrated as it leaves the vein, and all the fluids are kept at body temperature during the necessary steps in the operation.

Dr. **J. H. RAWLINSON** presented the subject from the surgical point of view.

Dr. JOHN HAY read a paper dealing with

Prognosis in Patients presenting a Rapid Heart Action.

Patients with rapid action of the heart could be classed into two groups: (1) those in whom the rhythm is physiological, and (2) those in whom it is pathological. In the first group the rapid action is secondary to such causes as emotion, effort, toxins, &c., and the prognosis depends on an accurate recognition of the primary cause. Dr. Hay referred to the rapid action in patients suffering from aortic regurgitation, and also to apyretic tachycardia of early tuberculosis, and discussed the combination of functional and organic diseases of the heart. In the second group he dealt with three conditions—paroxysmal tachycardia, auricular flutter, and auricular fibrillation—and described typical cases, defining the general principles on which prognosis depended.

NORWICH MEDICO-CHIRURGICAL SOCIETY.

Exhibition of Cases and Specimens.

A CLINICAL meeting of this society was held on March 1st, Sir HAMILTON BALLANCE, the President, in the chair.

Dr. W. TYSON showed a girl on whom he had operated for Thrombosis of the Lateral Sinus. He had opened the mastoid cells to relieve symptoms of severe pain in the right ear, tenderness over the mastoid, foul discharge from the ear, and an oscillating temperature. After the mastoid operation she had a severe rigor, and he therefore explored the lateral sinus, having first tied the internal jugular vein in order to limit the infection. He removed a foul-smelling clot from the lateral sinus, and the patient made a good recovery.

The PRESIDENT congratulated Dr. Tyson on the result of the case, and remarked that there were several symptoms which were pathognomonic of lateral sinus thrombosis, including a history of purulent discharge and a sudden onset, with oscillating temperature, vomiting, repeated rigors, local tenderness, and stiffness of muscles.

Dr. W. WYLLYS showed a patient in whose orbit a Mule's globe which had been inserted several years previously had suddenly burst. He removed the fragments under an anæsthetic and inserted another Mule's globe, which, however, also got broken. After eight days he had to remove some fragments, and as the eye was now septic he determined to try the effects of yadil as an antiseptic, using a solution of ʒi. to 4 oz. of water, which was instilled every two hours for two days, when another globe was inserted with satisfactory results. He brought the case forward chiefly to show the beneficial results of what he considered a suitable antiseptic to be used where a plastic operation was undertaken in an inflamed area.

Dr. E. B. HINDE showed a case of Hemianopia with Visual Hallucinations, and also related a peculiar case of Sudden Prolapsus Uteri after delivery, in which the patient stated that she had felt a sensation of "something giving way inside her," and the midwife and another nurse reported that they had heard a loud noise as of something giving way immediately after the birth of the child.

Dr. TYSON showed a specimen of Adeno-carcinoma of the Cæcum, for which he had performed resection of the bowel.

Dr. V. H. BLAKE showed the Kidneys from a Man with Polycystic Disease. At the autopsy the liver was found covered with tiny cysts, and the kidneys were composed entirely of cysts. It was remarkable that the subject of this disease had lived an active life for over 70 years, that there had been no albuminuria, and the only signs of uræmia were occasional attacks of vomiting.

Dr. DARLEY WYNNE read notes and showed microscopic slides of an unusual case of Endothelioma of the Leg, with presumed recurrence in the brain. The patient was a woman aged 70, who for some years had suffered from extensive varicose veins in the right leg. A tumour about the size of a small walnut developed over the internal saphenous vein, about half-way between the saphenous opening and the knee. This was at first considered to be a thrombosis in the vein, an opinion shared by Mr. J. Burfield in consultation. Mr. Burfield operated and found a series of small tumours growing from the vein, which were at first thought to be melanotic sarcomata, but a microscopic examination by Dr. Claridge showed that the nature of the growth was endothelioma, growing from the endothelium of the vein. [Microscopic slides of the tumour were exhibited.] The subsequent history of the case was interesting. The patient never had any further trouble with the veins and enjoyed good health for 18 months, when she was one day suddenly seized with vomiting and rapidly became unconscious and died three days later. There had been some prodromal symptoms, such as left-side headache and dimness of vision. The left pupil was widely dilated and inactive to light, the right normal, and there was marked left optic neuritis. Unfortunately no post-mortem could be obtained, but from the association of optic neuritis, dimness of vision, headache, and vomiting Dr. Wynne came to the conclusion that the patient's death was due to a recurrence of the tumour in the brain. Dr. Claridge agreed that there probably was a secondary growth in the brain connected with some of the blood-vessels, but thought the final issue was due to hæmorrhage, possibly from a vessel involved in the growth.

Dr. G. P. C. CLARIDGE exhibited a Uterus which was the subject of Chorion Epithelioma. The patient had suffered from uterine hæmorrhage for two years and was curetted by Mr. Burfield, who afterwards removed the uterus, as curetting had given no relief. The uterus contained two tumours, which were found on microscopic examination to be chorion epithelioma. There was also a tumour in the vagina, probably secondary.—Mr. BURFIELD, the PRESIDENT, and other speakers discussed the connexion between chorion epithelioma and hydatid mole, as it had been stated that nearly half the cases of chorion epithelioma were subsequent to hydatid moles, an opinion which did not meet with general agreement.

Dr. J. DUNCAN HART exhibited an Ovarian Dermoid, the clinical history of which was interesting from the point of view of diagnosis. The patient was a young, healthy, robust woman of 28 who was taken suddenly ill with severe pain in the epigastrium and tenderness on deep pressure, but no rigidity of muscles. Some albumin was found in the urine, but after a fortnight's illness she apparently recovered. As the abdominal tenderness persisted she was sent to see Mr. Burfield, who found tenderness in the appendix region, and took her into hospital, where she was X rayed by Dr. A. J. Cleveland, who gave it as his opinion that there was a calculus in the right ureter. On operation the appendix showed signs of recent inflammation, but no stone was found in the ureter, which was quite free. An ovarian dermoid cyst on the right side was found and removed. On examination of the contents of this cyst after removal a small perfect tooth was discovered, and it was this foreign body which had caused the shadow on X ray examination and had been mistaken for a calculus in the ureter.

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY AND BRITISH MEDICAL ASSOCIATION.

Venereal Disease Commission to the Far East.

A JOINT meeting was held on March 24th in the Firth Hall of the University. Dr. RUPERT HALLAM was the lecturer, and the chair was taken by Dr. F. J. SADLER.

Dr. Hallam gave a short account of his journey round the world as the medical member of a Commission which was dispatched to the Far East by the National Council for Combating Venereal Diseases with the approval of the Colonial Office. The Commission first visited New York, arriving there early in November, 1920, where Dr. Hallam had the opportunity of seeing several of the well-known skin and venereal clinics. It is interesting to note that the majority of patients pay for their treatment, but that necessitous patients are able to obtain free treatment. Compulsory notification and treatment of venereal disease has been in force for more than a year, and the consensus of opinion is that this has not acted as a deterrent to patients to seek treatment. He next visited the New York State Laboratory at Albany, a large, splendidly equipped building presided over by Dr. Wadborough.

The Commission journeyed across Canada, making brief stays at Toronto, Winnipeg, Regina, and Victoria, where meetings were held under the auspices of the Canadian Council for Combating Venereal Disease. In Japan useful information was obtained from the officials of the Government Health Department, and visits were paid to two hospitals in Tokio. At the invitation of the Shanghai Municipal Council the Commission conducted a campaign of public enlightenment in that city, and Dr. Hallam gave a series of lectures and demonstrations to the medical practitioners in the diagnosis and treatment of venereal disease. The incidence of both syphilis and gonorrhœa among the Chinese in the seaport towns is very high, and before the visit of the Commission there was no treatment by modern methods available for them. The Commission conducted a similar campaign at Hong-Kong, Singapore, and Colombo, and in each of these ports recommended that the free diagnosis and treatment of venereal disease should be provided.

Dr. Hallam afterwards showed a kinema film produced by the American Hygiene Association, New York.

Reviews and Notices of Books.

HYGIÈNE ET RÉGIMES.

By G. H. LEMOINE and F. RATHERY. Paris: A. Maloine and Fils. 1921. Tome XXVIII. Pp. 390. Fr.28.

A COMPREHENSIVE work is being published at present in France under the direction of Drs. Émile Sergent, L. Ribadeau-Dumas, and L. Babonneix, dealing with medical pathology and applied therapeutics. The twenty-eighth volume in the series, written by Dr. G. H. Lemoine and Dr. F. Rathery, is devoted to hygiene and dietetics. Dr. Lemoine discusses the effect upon health of environment—air, light, drinking-water, food, the disposal of refuse, prophylaxis, and hospital provision; but he does not touch upon the personal note which is pervading preventive medicine in this country. He has collected and clearly sets forth up-to-date information on the subjects dealt with. The work is essentially a text-book for reference which reproduces accepted opinions. But occasionally the author lags behind knowledge, as, for instance, when he ascribes the harmful rôle of confined air in living rooms to anoxæmia due to lack of oxygen in the air, and when, in the same connexion, he claims that the presence of an excess of carbon dioxide must above all be looked upon as an indication of human contamination. Our readers hardly require to be reminded of the investigations of Haldane and of Leonard Hill, which entirely discount such views. Appreciation is expressed of our own garden cities, and we are here able to recognise familiar places under such noms de plume as Boudary Street, Port-Sunglith, and Lecht-worth. This portion of the book is accompanied by a useful bibliography of works published for the most part in France, of which hygienists in this country may be unaware.

Dietetics are discussed at considerable length by Dr. Rathery; indeed, half the volume under review is devoted to the subject, the first portion dealing with food in health, and the second with food in disease. Food has during recent years, especially in war-time, received so much attention that a work summarising available knowledge must be of value. But the author appears to be unacquainted with much that has been done in this country and the United States, particularly by Greenwood and by Benedict, to determine the energy requirements of various classes of the community and establish the cost of living. Gautier's standard, a distinctly low one, is given for the daily number of calories needed, rather than that of the Food Committee of the Royal Society, and no effort is made to indicate the needs of different occupations. Similarly, when vitamines are under discussion, while fat-soluble A and water-soluble B are described the absence of any reference to the antiscorbutic factor is notable.

Apart from such omissions knowledge relating to food is well and fully stated, but the case for the exposition seems somewhat discounted by the conclusion that "la question de régime est ici comme dans beaucoup d'autres cas, questions d'espèces et de personnes et un exclusivisme trop étroit paraît devoir être écarté." The position, of course, is different in the case of dietary in disease; this subject is dealt with at length for various maladies. Those seeking information on the subject are more likely to turn to text-books dealing with the diseases in question; but writers of such text-books may welcome an expression of opinion such as is here given by a specialist on food. This part of the book suffers from frequent quotation of authorities without reference to their original papers and from the absence of any bibliography. The whole volume may be recommended as a useful book of reference, but its value is seriously impaired by an unusually sparse index which is not even always accurate. Any index may be said to be better than no index at all, but when a book is carefully written and documented, and on the large side, a good index is an asset.

SYNOPSIS OF SURGERY.

By IVOR BACK, M.B., B.C. Cantab., F.R.C.S. Eng., and A. TUDOR EDWARDS, M.C.Cantab., F.R.C.S.Eng. London: J. and A. Churchill. 1920. Pp. 480. 15s.

THIS is frankly a cram-book, but a quite sound cram-book, as the authorship would lead us to expect. The authors appeal to those students who are not industrious enough to make a complete synopsis for themselves, and leave the more conscientious to work out their own salvation. The subject-matter is clear, complete, and modern. Above all, its perspective is good, and there are few candidates for an examination of the standard of the final M.B. who would not be the better for running through its pages. In the account of each lesion its cause, pathology, signs, and treatment are given with directness and refreshing truth. There is no nonsense about memorising from 9 to 14 causes for a disease which has at most one or two. The sections on treatment, although short, are particularly complete and leave little to be desired; though many surgeons would object to the statement that cholecystectomy is only indicated in gangrene or malignant disease of the gall-bladder. Where all is good it is unnecessary to pick out portions for praise, but there are many small points that he who reads may note with advantage. The chapter on shock is well up to date; burns and scalds come under the heading of "Gangrene due to heat." It is well to see in print that nitrous oxide anæsthesia is contra-indicated in cellulitis of the neck, as its popularity as an anæsthetic is likely to cause this to be overlooked. We note one solecism, "parotiditis," which appears to be negatived by its derivation, and has no beauty either as a written or spoken word to recommend it.

"Synopsis of Surgery" before an examination should be looked on as a kind of vacuum cleaner to remove cobwebs and as a purge for verbosity.

DISEASES OF THE NEW BORN.

Diagnostik der Kinderkrankheiten. Mit besonderer Berücksichtigung des Säuglings. Von Professor Dr. E. FEER, Direktor der Universitäts-Kinderklinik in Zurich. Berlin: Julius Springer. 1921 With 225 illustrations. Pp. ix. + 276. M.40.

SINCE the appearance of a book on the Symptomatology of Children's Diseases by the late Professor Filatov, of Moscow, some thirty years ago, there has, as far as we know, been no book published which adopts the semiotic method, so useful to the practitioner of pædiatrics. The volume before us, written by an experienced clinician and teacher, is an attempt to supply this want. The author starts with a few brief remarks on history-taking, and then goes on with a very generously illustrated account of the facies and everything that can be learned therefrom. Disturbances of growth, discolourations and other abnormalities of the skin, derangements in structure and function of muscles, glands, bones and joints are then illustrated and described. The next 146 pages are devoted to a discussion of symptoms and of the methods of examining the chest and abdomen and detecting any abnormalities within those cavities. The blood and the various symptoms associated with urogenital diseases are then dealt with, and lastly there comes a consideration of the examination of the nervous system and the symptomatology of nervous diseases. The final 15 pages are taken up with pyrexia, the diagnosis of typhoid and tuberculosis, and the causes of sudden death in infancy.

In each section the salient anatomical and physiological peculiarities of the organs or systems are given. The book is profusely illustrated with photographs which are mostly, but not always, helpful. A picture (Fig. 186, p. 164) of a healthy, smiling child, meant to illustrate the needless anxiety of a devoted mother, has no clinical value. Fig. 205 on p. 230 is a poor photographic illustration of severe opisthotonos. Certain redundant photographs might well have been replaced by a few blood pictures, and the inclusion of diagrams of the lesions in various nervous diseases would have been useful in illustrating the methods of differential diagnosis, to which, by the way, Professor

Feer gives little space. Brief descriptions of some of the more recent clinical methods would have been helpful. For example, though the increased fragility of the red cells in acholuric family jaundice is noted, the clinical method of testing its presence is not even mentioned. In the paragraph on Babinski's sign the author accepts the common statement that this sign is nearly always positive in infants under 1 year. Recent work indicates that although a positive Babinski phenomenon is of no pathological significance in young infants the majority of them show a flexor plantar response in type even in the youngest infants. We criticise only minor points. The volume as a whole is good and serviceable.

INITIATIVE IN EVOLUTION.

By WALTER KIDD, M.D., F.R.S.E. London: F. H. and G. Witherby. 1920. Pp. 252. 15s.

THE failure of Lamarckism to prevail against Weismannism lies in the difficulty experienced by its supporters in adducing facts in its favour which cannot be brought, by those opposed to them, within the range of action of natural selection, or shown to possess some probable useful end. The followers of Weismann, on the other hand, are faced with the difficulty—which would seem almost insuperable—of proving that the evidence brought forward by their opponents has reference to facts which cannot be attributed to the inheritance of acquired modifications. Each party in this stalemate is therefore waiting for "something to turn up," and, in the meantime, taking every new fact which appears as supporting its own contentions, largely because the other side is unable to prove a counter claim. Dr. Kidd is a convinced supporter of the tenets of Lamarck on the inheritance of acquired characters, and has been collecting for many years evidence in favour of these tenets which he has now made public in this book. To reduce the opposing utilitarian argument to a minimum, or to obviate it completely, he has concerned himself only with the small things which "don't matter," the arrangement of hair-streams, papillary ridges and flexure lines, bursæ, and so on. The examples which impressed us were those in which the effects of harness on draught horses were transmitted to their foals; this line of observation seems to us of great value, differing in its direct simplicity from the other extensive observations, such as, for instance, those on lines of hair streams, which depend for their force on what is, after all, an assumption concerning human descent. We do not give detailed reference to the ground which is covered by this volume, but it may be said that the examples produced by its author seem to vary in their freedom from the range of "utilitarian" attack; this is, perhaps, more evident in the last few chapters.

The book is eminently readable, and the illustrations introduced are clear and appropriate. We think that Dr. Kidd has done good service to his cause in producing the results of his investigations and has brought forward evidence of considerable value, even though, as he says, it has only to do with humble and lowly things. Whatever views they may hold on the general question, or whatever the value they may allow to Dr. Kidd's individual instances, we think that readers of the work will find in it much food for reflection and a great deal to stimulate their interest.

THE AUTHOR PSYCHOLOGIST.

Woman. By MAGDALEINE MARX. Translated from the French by A. S. SELTZER. London: George Allen and Unwin, Ltd. 1921. Pp. 288. 7s. 6d.

Hunger. By KNUT HAMSEN. Translated from the Norwegian by GEORGE EGERTON. London: Duckworth and Co. 1921. Pp. 310. 8s. 6d.

EVERY author worthy the name is a psychologist, though he need not necessarily be steeped in the jargon of the text-books. Some quite modern professional psycho-analysts are fond of illustrating their theories from the fiction of an age that knew them not. In Shakespeare may be found problems for analysis as complicated as those presented in the clinics of an asylum. With time comes change, and the authors of to-day seek new methods wherewith to clothe in flesh the complex personalities created by a skilful adjustment of their own observation and experience. Two recent translations of books already famous in their original tongue give interesting illustration of one of these modern methods. Each is written as an autobiographical narrative, the first so strictly that even the conversation of the foils to the narrating character is practically eliminated. In both one is reminded of a trick of the kinematograph in which the hero goes through his evolutions in the centre of the screen, whilst the houses, the road and its traffic, pass mistily across the background. It seems almost inevitable under these circumstances that the central figure will appear self-conscious, over-assertive, and tiresome, and, in spite of the undeniable skill with which this danger is combated, the impression does in both cases remain. Neither is it to be gainsaid that the reader's eye is focussed from start to finish upon the evolutions of the author's synthetic puppet—and that is, no doubt, just as it was meant to be.

"Hunger" is more than a study of starvation; it is a text-book on the physiology as well as on the psychology of destitution. It expounds the eccentricities of the fasting stomach as well as those of the under-nourished brain, and ranges the city of Christiania in search of new stimulants to provide varying reactions of these two to their environment. To say that one grows hungry in reading would be faint praise, one is gnawed by a despair of life such as no previous experience has ever unfolded. In these days the accomplishment is as useful as it is brilliant.

The writer of "Woman" has a more difficult task. If we are to believe Henri Barbusse, who has written the introduction, this book expresses what has never been exactly expressed before. It expresses woman. But what woman? Someone very different certainly from the numerous female decorations who flit across the background. Someone certainly unlike anything our grandfathers would have admired. A type, in short, neither of women of all time nor of all women to-day, but of the sort of women whom the writer most admires among her contemporaries. As such the heroine is not incongruous; she is even a little lovable and very much to be pitied. But she will pass. She is no more the woman of a hundred years hence than of a century ago. Already we suspect she is a little out of date. We cannot imagine her paying the wages of a mentally deficient Breton girl to act as servant in a three-room flat—not with rents as they are in Paris to-day.

That both books are well worth reading is due in no small measure to the skill of the translators who have succeeded in preserving an unusual style in both cases without apparent effort. "Hunger," however, should be revised for some minor alterations if it is printed in English again. On page 37, for example, "not a little bewildered" should surely be "not the least ......," which would alter the sense helpfully.

SYMPTOMS AND THEIR INTERPRETATION.

Fourth edition. By Sir JAMES MACKENZIE, M.D., F.R.C.P. London: Shaw and Sons. 1920. Pp. 331.

THE study of clinical medicine has for several years been overshadowed by the study of clinical methods and, as a result, an undue significance is often attached to the data obtained by the use of the more modern clinical methods, such as blood examination, blood-pressure measurement, and radiography. To an even greater extent the recent advances in bacteriology, immunology, and biochemistry have eclipsed the interest attached to the study of symptomatology. Sir James Mackenzie restores the balance and directs research along new lines in old fields by strongly advocating the more exact study of symptoms in disease; he is especially qualified to preach this gospel because of the success he has achieved in advancing the knowledge of medicine by the clinical investigation of irregularities of the heart and the distribution of hyperæsthetic zones in disease. In this book the study of symptoms is taken a further stage; the reader is asked to pause for a moment in the constant effort to isolate new symptoms of disease and to turn his attention to a study of the interpretation of the numberless symptoms already known.

The author aims at establishing the fundamental principles that underlie the production of symptoms in order that the confused mass of detail now included under symptomatology may be simplified in terms of general principles or Laws of Nature. Professor Karl Pearson would feel some surprise at the author's idea of a "Law of Nature," and the paragraphs that discuss general principles and laws of nature require editing by someone acquainted with *The Grammar of Science*. In these opening chapters certain important definitions are framed; thus the word "symptom" is defined as the reaction of the tissues of the body to a noxious agent, and so includes advisedly both signs and symptoms (using the words in their more ordinary sense). As a result of framing the definition so broadly, it follows that a mitral systolic murmur or the absence of free hydrochloric acid in a test-meal examination are symptoms of disease, and the common distinction between subjective and objective phenomena is lost. But this distinction is sometimes required for the sake of lucidity, and the author is forced to acknowledge it in using the phrase "physical signs" in contra-distinction to "symptoms." The definition of pain is also difficult to accept, for it excludes the possibility of a sensory cortical representation of vegetative nervous impulses by referring all painful sensation to the peripheral distribution of cerebro-spinal sensory nerves in the external body wall.

The main thesis of the book turns on the discovery that the majority of symptoms of disease are disturbances of normal reflexes; many illustrative clinical cases are given in the text, and the observations and train of thought that led to this discovery are given in an appendix. This thesis loses none of its interest in the fact that this discovery has been made before. We owe most of our knowledge of reflex action to the work of Professor C. S. Sherrington, and he put the whole matter in a nutshell when he defined pain as the psychical adjunct of a protective reflex. The author maintains that the prevailing ignorance of the nature and interpretation of symptoms is due to a lack of appreciation of their significance and importance, yet the study of medicine has concerned itself in the past with little else, and since the time of A. von Haller (1752) physiologists have laboriously worked at the same subject. The fact really is that the anatomy and physiology of the vegetative nervous system have not been sufficiently known owing to the inherent difficulties of its study, and that it is due to the work of such men as Langley, Anderson, and Sherrington that a new dawn is breaking on clinical medicine. Other workers in this field are scarcely referred to, and the book would be improved if some of the knowledge possessed by such men as Cannon, Hurst, Higier, and Pottenger were mentioned.

Despite these criticisms we do not lose sight of the fact that the book is pioneer work and stimulating to read. It contains much original observation, and marks the slow but sure step of an original investigator. A careful study of it will repay every student and practitioner of medicine, and will open their eyes to the opportunities that lie all around of advancing medical science and professional art.

WHY DO WE DIE?

By T. BODLEY SCOTT, M.R.C.S. Eng. London: T. Fisher Unwin. 1921. Pp. 123. 6*s*.

THE real title of this book is given in the first sentence—namely, "Why do we die so long before our time?" and the answer is, "Because of arterio-sclerosis." Dr. Scott pleads for a more rational way of living, all through life, but especially in that period of life which comes after 40 years, and his advice is sound. Temperance in eating, as much as in drinking, work, not mainly for selfish objects, regulated exercises, and contentment, are, he says, and with truth, the best ways of staving off arterio-sclerosis with its accompaniment of raised blood pressure. His chapter on The Way of Safety is good, but as we so often notice in books of this class when talking about alcohol, not enough stress is made upon the difference between alcoholic drinks, such as light beers or wines, and spirits. We are sure that for everyone, and especially for old people, light beer or light sherry or claret is a far safer and profitable drink than either whisky or brandy, though the latter, if genuine and old, is better than the former. Another word of warning which we must give is that, as this book is evidently intended for the laity, the laity should remember that no preparation of thyroid should be taken except under strict medical supervision. Taking it all round, the book is useful.

JOURNALS.

Journal of the Royal Army Medical Corps, February and March.—In the February issue J. B. Orr and J. P. Kinloch suggest that proteid food stimulates increased body metabolism and rise of temperature, for they observed that the same short task done fasting or soon after a meal was accompanied by a greater output of energy, a greater production of calories, if the meal was preponderantly proteid.—Professor L. S. Dudgeon and A. L. Urquhart, in a paper on the Paratyphoid "C" Bacillus, mention a case of enterica due to this bacillus occurring in St. Thomas's Hospital in March, 1920. Lieutenant-Colonel P. H. Henderson, telling of medical conditions in Transcaucasia, which extended from the Caspian to the Black Sea, mentions as the prevalent diseases, malaria, typhus, smallpox, relapsing fever, dysentery, cholera, enterica, and the three venereal diseases. The British garrison suffered severely from malaria. Prophylaxis of venereal disease with potassium permanganate and calomel cream was of definite value if well carried out. The other diseases do not seem to have seriously affected our soldiers.—Captain W. J. Rutherfurd tells how frequent are the risks run by men in tunnelling companies from carbonic oxide poisoning consequent on the use of explosives in mining work.—Ex-Captain C. Samut and Captain W. T. Munro relate several cases to show that autogenous vaccines may arrest profuse and diffused suppurations and ulceration in apparently hopeless cases.—Captain H. J. B. Fry narrates at greater length the remarkable history of a projectile in the blood stream which was recorded in THE LANCET, 1920, i., 13. A gunner was wounded by a bullet half an inch below the left anterior superior iliac spine. He thought he was hit in the foot, but on examination there was found a small wound as noted above. The bullet had found its way to the left external iliac artery and had caused an arterio-venous aneurysm with the left internal iliac vein. The left leg was congested, swollen, and pulseless. It became gangrenous, was amputated, and ultimately the stump, too, showed gangrene. Patient's pulse had been 100-120, but became 136; pressure was low. Respiration rose to 60 or 70, and he died in coma. The bullet had passed up the great veins, through the heart (quite painlessly), and was found in a descending branch of the left pulmonary artery, where it was impacted as an embolus, causing two infarcts in that lobe. At the post-mortem there was marked passive congestion of the abdominal organs. Patient had bled into his venous system through the arterio-venous aneurysm. There had been no infection of the blood stream.—Lieutenant-Colonel J. H. Douglass and Captain H. Carlton report from Sierra Leone a case of blackwater fever cured by injections of trypsin and amylopsin into the gluteal muscles. This treatment is said to be useful in all malarial cases, especially first attacks in which sexual forms have not appeared, also in cerebral malaria and blackwater fever.—There is also a most useful paper on "India from the Mem-Sahib's Point of View," by Mrs. P. Hope-Falkner, which should be read by all before taking families to India. It discusses expenses, children, servants, food, clothes, furniture, and trunks, and is most instructive.

The issue for March opens with the paper on Tick Fever by Major-General Sir William Leishman, which appeared in THE LANCET of Dec. 18th, 1920, p. 1237.—Major Athelstane Hill contributes a careful clinical research on "Upward Displacement of the Diaphragm, with special reference to the diagnosis of Amœbic Hepatitis." He concludes that inflammation, in immediate contact with any part of the diaphragm (amœbic hepatitis, malarial perisplenitis, perinephric abscess), causes a reflex dilatation of that leaf of the diaphragm with which it is in contact. This may be recognised by percussion or X rays, as the upper surface of the liver rises above its normal position. This dilatation goes on to stasis, the chest cavity is lessened, the tension of the lung reduced, and predisposition to serious intrathoracic infections is increased. In endemic centres amœbiasis and malaria are the commonest causes of right- and left-sided dilatation respectively. In acute cases the use of emetine is imperative, laboratory confirmation not being awaited, since "amœbiasis" is commoner in endemic centres than is indicated by the prevalence of dysentery or the results of laboratory investigation." The new physical signs described are illustrated by excellent diagrams.—Lieutenant-Colonel H. M. Perry and Captain R. C. Robertson describe a combined influenza-pneumococcus-catarrhalis septicæmia of the mouse; the lesions in the lungs are those found in human influenza, a very important observation.—Major Julius Burnford has an interesting paper on influenza as seen in France, Woolwich, Salonica, and the Dardanelles in 1918. An earlier paper by this author is quoted by Sir George Newman in his introduction to the Influenza Report, but does not appear to be included in the bibliography there. Major Burnford very wisely draws attention to the facilities given by crowded troop trains and transports for the spread of epidemics. Cyanosis is of great prognostic value, yet some badly cyanosed cases do recover. The albuminous, possibly antitoxic, effusion into the lung may pour out of the patient's mouth while by it he is being veritably drowned. The striking post-mortem appearance is the extreme friability of the lung tissues, and, with that, emphysema. Glands of thorax and neck are much enlarged. He tried many treatments, but ultimately opium for sleep and poultices for pain, and advises that patients be kept warm but in the open air, with all the food they can take, and stimulants. Camphor, atropine, digitalis, strychnine, and expectorants disappointed him; 15 gr. of Dover's powder on admission became the routine, with linseed poultices when evidence of pneumonitis appeared. Major Burnford would appear to have treated a case successfully with the serum of recovered patients before that had been tried elsewhere as mentioned in the Influenza Report on p. 95. This paper was sent in two years ago.

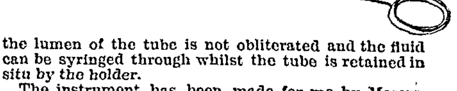
British Journal of Ophthalmology, January to March, 1921.—In the January number there is an interesting account of a case of Melanosarcoma of the Bulbar Conjunctiva, by Dr. L. K. Wolff and Dr. H. Deulman, of Amsterdam. The growth originated in a black pigment spot which had been noticed by the patient herself for ten years. It was removed and the eye was treated with X rays. Recurrence of pigmentation took place, however, and it was considered safer to excise the eye, in spite of the fact that it possessed good sight. The infiltration of the sclera found on examination of the excised eye justified the decision. Dr. James Taylor relates some cases of Encephalitis Lethargica of peculiar interest to ophthalmic surgeons.—In the February number the causation of Detached Retina is discussed by Mr. Charles Killick. Excluding cases in which some definite cause can be assigned, most of which are either traumatic cases or cases associated with albuminuria, all others, including myopic ones, are termed "idiopathic," and these are all attributed to bands formed in a degenerated vitreous forming adhesions with the retina, the contraction of the bands causing either tears in the retina or a detachment without tears. This theory, which is by no means new, is probably the correct one for a proportion of cases. When one considers, however, the extreme rarity with which tears of the retina can be demonstrated ophthalmologically, one cannot but doubt whether they play such a large part in the causation of detached retina as is maintained. Doubtless in a certain proportion of cases they do occur, but if they are so frequent as alleged, why are they not more often seen? They might, it is true, well escape notice when in the region of the ora serrata. On the other hand, in the few cases where they are seen at all the appearance is unmistakable.—In the March number Dr. Harrison Butler, after giving some examples of idiosyncrasy, concludes with the wise dictum that when our patients tell us that they react abnormally to certain drugs, we must act upon their information, however unusual it may appear.—In the correspondence section of the same number a suggestion is put forward by Mr. William Lang as to the causation and treatment of migraine. His theory is that an attack is started by a wave of contraction of the cortical occipital vessels, causing partial or complete hemianopia; that the wave of contraction is followed by dilatation of the vessels, causing intense headache and vomiting. In accordance with this theory he recommends to his fellow sufferers the treatment of hot fomentations to the back of the head when the attack is beginning, followed by cold applications as soon as the headache begins.

British Journal of Children's Diseases. Vol. XVIII. January to March. Edited by J. D. ROLLESTON, M.D.—In a paper on Malaria in Children at Smyrna a well-known Greek pædiatrist, Dr. Solon Veras, states that though malaria is very prevalent throughout Asia Minor the town of Smyrna was relatively immune before the war, only 3 per cent. of the children brought to his out-patient department from 1906-1913 suffering from the disease as compared with 11 per cent. from June to December, 1920. The largest proportion of cases occurred between the ages of 1 and 2 years. The form of malarial fever observed was the quotidian type, which is the most frequent at Smyrna. A characteristic tertian was met with in only 8 out of 88 cases seen between June and December, 1920. Dr. Veras has never seen the quartan type. Concetti's statement that malaria in children has a greater tendency to chronicity than in the adult is confirmed by the present series, in which 66 of the 88 cases belonged to the chronic type. The tendency of malaria to affect the nervous system in children is exemplified by the frequency of convulsions as the initial manifestation and the tendency of the disease to simulate meningitis. Alimentary disturbances, which may be of a very severe character, are a frequent complication of malaria in young children, especially in Asia Minor, where enteritis is the chief cause of infantile mortality. In acute forms of the disease Dr. Veras has obtained the best results by hypodermic injection of quinine, 0·25 g. or 0·50 g. of the hydrochloride, or preferably, owing to its being less painful, the formate of quinine, being given at a time. In the chronic form he recommends an Italian preparation known as *esanofele*, which is a mixture of quinine hydrochloride, arsenic, and citrate of iron, in the form of pills or a syrup.—In a paper on the Cœliac and Allied Types of Infantilism: A Retrospect and Bibliography, Dr. Reginald Miller reviews the literature from 1888, when the late Dr. Samuel Gee published his paper on the cœliac affection, down to the present year.—In his notes on Mongolism Dr. Hugh Thursfield records his observations on 42 Mongolian imbeciles seen at the Hospital for Sick Children between the beginning of 1912 and 1916. After discussing possible ætiological factors, such as the frequency of the condition, the place of the Mongol in the family, the age of the mother, health during pregnancy, history of miscarriages, character of the labour, infective diseases and prevention of conception, Dr. Thursfield gives figures as to the frequency of cardiac and other defects among his cases. Of 25 patients whom he was able to trace, 14 were dead, the causes of death being chiefly bronchopneumonia and diarrhœa. The oldest survivor was aged 15 years, the youngest 6 years, and the rest between 6 and 12 years. None of them showed the least tendency to become normal with increasing years, though the more obvious signs of mental defects were certainly lessened. Like certain French physicians who have kept Mongols under observation for a long period in institutions, Dr. Thursfield is convinced that both physical and mental improvement can be derived from small doses of thyroid, though there is no prospect of obtaining the effects commensurate with those observed in the cases of cretins.—A Case of Hemi-hypertrophy is reported by Dr. E. George Hall, with comments by Dr. F. Parkes Weber.—Dr. W. M. Feldman writes on the Nature of the Plantar Reflex in Early Life and the Causes of its Variations, in a paper which is an abstract of his London M.D. thesis, his observations being based on 500 cases from birth up to 7 years.—A Case of Œsophagectasia in a Child is reported by Dr. D. H. Paterson. The patient, a boy, aged 4½ years, had vomited his food on and off since birth. X rays showed a dilatation of the œsophagus in its upper part and a constriction below. An exploratory operation was performed, and a finger was readily passed through a small hole in the stomach up the œsophagus without any stricture being found, showing that the condition was due to spasm.—Mr. E. E. Hughes records a Case of Hydatid Disease of the Liver in a Child, the patient being a boy aged 11 years. The diagnosis of hydatid cyst was confirmed by operation, at which a pint of fluid containing characteristic hooklets was removed. The abstracts from current literature are devoted to diseases of the newborn, diseases of the blood, and diseases of the liver.

New Inventions.

CATHETER-HOLDER FOR INTRA-UTERINE TREATMENT OF GONORRHŒA.

IN order to facilitate the introduction of the catheter into the fundus uteri I have devised the catheter-holder here illustrated. It is a light, handy instrument and has the advantage that, owing to its size and to the bend in the shank, the line of vision of the catheter is not obscured. When the catheter has been inserted the lumen of the tube is not obliterated and the fluid can be syringed through whilst the tube is retained in situ by the holder.



The instrument has been made for me by Messrs. J. H. Montague, 69, New Bond-street, London, W. 1.

REMINGTON HOBBS, M.D., M.R.C.S.,
Medical Superintendent of Kensington Infirmary.

# Reports and Analytical Records
FROM
THE LANCET LABORATORY.

COLLOSOL FERROMALT WITH CASCARA.

(BRITISH COLLOIDS, LTD., THE CROOKES' LABORATORIES, 22, CHENIES-STREET, LONDON, W.C.)

OUR analysis shows that this preparation contains 0·018 per cent. of iron (0·028 Fe_2O_3) in a colloidal state which it is claimed is absorbed without the usual disadvantages associated with iron, such as constipation and dyspepsia. To ensure a laxative action each fluid ounce contains 2 gr. of cascara extract. Collosol ferromalt is agreeable to the palate, and it has been prepared so as to contain the accessory food factors essential to cell metabolism. A case is cited in which an anæmic woman with a colour index of 68, after three months' treatment with collosol ferromalt, increased her index to 90. Other organic and inorganic iron preparations had failed. In THE LANCET for May 15th, 1920, we drew attention to the increasing interest which is being taken by practitioners in colloidal medications.

DIMOL: A NEW INTESTINAL DISINFECTANT.

(THE ANGLO-FRENCH DRUG CO., LTD., 238A, GRAY'S INN-ROAD, LONDON, W.C.)

The claims made for this new intestinal disinfectant are put forward on the favourable clinical experience of specialists in this country and in the United States. The preparation has been introduced by Captain Ainslie Walker. It is possible to destroy all bacteria in the fluid contents of the intestinal tract with a duodenal douche of dimol, but the dosage recommended in the form of tablets or pulverettes (2 to 4 after each meal) is so regulated that the *B. coli* normally present are not affected, a fact which can only be ascribed to their greater powers of resistance. In this way all apprehension of digestive disturbance by its administration is avoided. The chemical constitution of dimol, $C_6H_2(CH_3)_2(OCH_3)OH$, reveals the presence of a phenyl radical, but this is not split off in its passage through the intestine; in other words, dimol is voided with the fæces, unchanged. Examination for phenol in the urine after a week's course of treatment gives a negative result. Tests made for us confirm a coefficient of 35·0 and the freedom from toxicity claimed by the manufacturers.

NEW SEASON'S COD-LIVER OIL.

(ALLEN AND HANBURYS, LTD., BETHNAL GREEN, LONDON, E.)

The manufacturers claim that this Norwegian oil is prepared from fresh and selected cod livers with the minimum of exposure to oxidation. The preservation of the fat-soluble accessory substance, to which is attributed much of the therapeutic value of cod-liver oil, is thus assured. On analysis the oil was found to have the customary constants. No deposit of stearin was observed on keeping at the temperature of melting ice.

(1) ENERGEN GLUTEN TAPIOCA; (2) ENERGEN ENRICHED PASTRY FLOUR WITH ADDED GLUTEN.

(THERAPEUTIC FOODS CO., ENERGEN WORKS, ROUNDWOOD-ROAD, WILLESDEN, LONDON, N.W.)

(1) We have isolated from this tapioca about 6 to 7 per cent. of powdered gluten, which is present as a fine brown powder; the tapioca itself is of clean and good quality. We consider the statement on the carton, recommending its use to diabetics, to be at least questionable. Because gluten itself is free from starch, the addition of a small proportion to tapioca—which is practically all starch—can do little towards mitigating the disadvantages of a starchy diet for those whose starch tolerance is low.

(2) We find on analysis that the total protein content of this flour is 18·3 per cent., and calculation shows that the gluten present is about 6 per cent. and cannot possibly exceed 10. No baking powder is present. The ash is 0·54 per cent. As in the case of "gluten tapioca," we do not follow the suggestion that the addition of this small quantity of gluten in any way enhances its value for the use of diabetics, and the expression "richness in gluten" is hardly warranted by the composition of the flour.

MENTHOFAX.

(BURROUGHS, WELLCOME, AND CO., SNOW HILL BUILDINGS, LONDON, E.C.)

Menthofax is a compound methyl salicylate ointment containing 50 per cent. of methyl salicylate, along with menthol, eucalyptol, and oil of cajuput. It is designed as a topical application for rheumatic, neuralgic, and other painful affections. Synthetic oil of wintergreen has long been recognised as a useful local analgesic and counter-irritant, and menthofax is an elegant form in which to apply it. It is put up in collapsible screw-topped tubes.

SOAPS.

(WM. LYND AND CO., BOWMAN-LANE SOAP WORKS, LEEDS.)

We have received three samples of soap: (1) Lynd's City Quick Washer; (2) Lynd's City Carbolic Soap; and (3) Lynd's City Soap. Our analyses of the first two named show the following percentage composition:—

	City quick washer.	City carbolic.
Water	25·8	29·1
Fatty anhydrides	67·5	65·7
Free alkali as Na_2O	nil.	nil.
Alkali (Na_2O) combined as sodium carbonate	0·02	0·02
Alkali (Na_2O) combined as soap	7·6	7.28
Phenol	nil.	1·00

Both these soaps are of good quality, well made, and free from caustic alkali and insoluble matter; they are suitable for the respective purposes for which they are intended.

"FULCREEM" PRODUCTS.

(PLAISTOWE AND CO., LTD., KING'S CROSS, LONDON, N.)

We have received for examination the following preparations:—"Fulcreem" Cake Flour, "Fulcreem" Custard Powder, "Fulcreem" Concentrated Egg Substitute, "Fulcreem" Cakies, "Fulcreem" College Pudding, "Fulcreem" Blancmange, and "Fulcreem" Baking Powder. These different materials are put up in a convenient form in tins or packets with full directions for use. "Fulcreem" cake flour consists of a flour and sugar mixture, currants, sultanas, and peel in appropriate amounts being separately enclosed in the containing packet. On the addition of margarine and egg all the necessary ingredients for a cake are present. The fruit is dry and free from stalk, and the flour consists of wheaten flour only. We find the sweetening material is cane sugar and not saccharin. We deprecate the use of the descriptive term "Fulcreem," as the erroneous impression will probably be conveyed to the minds of most purchasers that the preparations are associated with full-fatted dried milk.

"Fulcreem" concentrated egg substitute when analysed was found to consist of a mixture of starch, colouring matter (turmeric), a phosphatic baking powder free from sulphate, and 8 per cent. of protein. Fat was not present. It is difficult to understand why such a preparation is claimed to be a substitute for eggs, as it does not even remotely resemble—with the exception of the colour—a genuine preparation of dried egg. The tin bears the inscription, "Not made from eggs but a complete alternative." We hold the opinion that a material differing so widely in its composition from eggs should not be described as a complete alternative.

"Fulcreem" baking powder is guaranteed free from alum. Our analysis confirms this statement, and shows that it is one of the well-known class of baking powders composed of acid calcium phosphate, bicarbonate of soda, and maize starch. An impurity sometimes found in this class of material, and against which a warning was issued in Dr. J. M. Hamill's report to the Local Government Board in 1911, is calcium sulphate introduced with inferior kinds of the acid phosphate. This we find on analysis to be absent, and the powder is also entirely free from arsenic.

THE LANCET.

LONDON: SATURDAY, APRIL 9, 1921.

Prevention of Heart Disease.

AMERICA has inaugurated a thoroughgoing campaign for the prevention and relief of heart disease. The movement originated with a number of New York physicians and social workers whose sympathies were aroused by the large and preventable waste of health and life among cardiac patients discharged as convalescent from the hospital wards, mainly attributable to the lack of facilities for ensuring efficient after-care. In 1911, as a tentative measure, an evening out-patient clinic was opened at the Bellevue Hospital, New York City, for the treatment of these patients, a number of social workers coöperating with the medical staff. Patients were visited at their homes, partly with the object of teaching them how to look after themselves and partly to assist them in getting employment suited to their physical capacity. The success of this combined work, in saving hearts from periods of breakdown and in enabling the patients to continue as wage-earners, was surprising. In 1912 a trade school was established in connexion with the clinic, and three years later came the incorporation of the Association for the Prevention and Relief of Heart Disease. This organisation has a central office, an executive secretary, and a large board of governors, subdivided into sectional committees having to do with the professional, economic, and social aspects of the problem. The first report of this Association, which now reaches us, contains information such as could only have been gathered by collective study. Much attention is devoted to heart disease in children, the association having been fortunate in obtaining the coöperation of the Board of Education, which authorised a study of the conditions in three schools situated near to children's cardiac clinics. Cardiac cases were all referred to the clinics for examination and classification, some being placed in segregated classes, others sent back to the regular school. At the clinics, which are directly in touch with convalescent homes, hospitals, dental clinics, and laboratories, records are kept bearing upon cause. Not the least important part of the work is the education of public opinion.

It is nothing less than deplorable that so little similar effort has been made in this country to stem the tide of heart disease; indeed, it is difficult to comprehend why this great source of death and disability should have remained so long neglected. In a recent leading article[1] attention was directed to the serious pathological and economic results arising from chorea and rheumatism; the same was pointed out by Dr. F. J. POYNTON and others at a debate of the Medical Society of London, and by Dr. CECIL WALL in his Bradshaw lecture. We then suggested that if some concerted action could be taken in regard to rheumatism far-reaching results might accrue. Local enterprise frequently has the effect of provoking national effort, and we have at least one example to emulate. The Royal Liverpool Country Hospital for Children at Heswall many years ago put into action a scheme using the local Invalid Children's Association as a clearing house. Children recommended for treatment by hospitals, school medical officers, or the workers of the association are collected, classified, and distributed to the institutions best adapted for their treatment, suitable rheumatic and heart cases being transferred to the Heswall Hospital. As in the American organisation, the social workers of this child-welfare agency carry out after-care work under the direction of the medical officers, the children being periodically brought to the clinics for observation. The death-rate from heart disease is small during childhood, but the incidence is high and accounts for many deaths in later years. Sir GEORGE NEWMAN'S report for 1919 indicates a tendency towards an increase in the number of heart defects of children attending the elementary schools. Between 1915 and 1919 there was a rise from 3·0 to 3·8 per cent. among boys, and from 3·3 to 4·9 per cent. among girls. These are high rates and betoken a large amount of heart disease among the people of the country. An examination of four of the reports of the medical officer of health of Liverpool taken at random between the years 1909–1916 showed an average of 962 deaths from heart disease, or about one-fifteenth of the total deaths. These included deaths from all types of heart disease and at all ages, but a considerable number of them had occurred in the early adult and middle periods of life, representing, no doubt, cases originating during childhood.

The plan followed for many years in connexion with the Heswall Hospital has been to cater for children suffering from conditions apt to promote heart disease—for instance, the minor and major rheumatisms, the so-called rheumatic types of chorea, and other diseases likely to be followed by cardiac infections. In addition, early cases of heart disease are admitted, but not the chronic ones. All of these children are treated for prolonged periods, many of them entirely in the open air, and it has been found by experience that at least 70 per cent. of them are discharged with sound hearts. Every child afflicted with chronic heart disease may be regarded as being crippled beyond repair. They frequently have quite good health for many years, during which much money and energy is expended upon them educationally. Later on it only too often happens that they break down under stress of work, and we find them swelling the numbers of the inefficient and crippled. Much scientific work is being done on the clinical side of heart disease, but not enough on the preventive aspect. The infectivity of rheumatism and of some of the choreas is still insufficiently recognised by the medical profession. Quite recently in a large boys' school a number of cases of typical acute rheumatism occurred in rapid succession, and there was every reason for believing that the source of infection was a carrier, himself presenting no symptoms. Dr. POYNTON has been preaching this doctrine of infectivity for many years, and its importance in relation to a preventive campaign is quite as great as that of the therapeutic and diagnostic measures which have been so thoroughly discussed, and to which the Brooklyn Cardiological Society is devoting its whole interest. The lessons derived from the work of the American Association and from the Liverpool scheme fully warrant us in promoting a national campaign against rheumatic conditions which are the ultimate cause of so much death and inefficiency.

Medicine in India.

WITH the meeting of the Legislative Assembly at Delhi has opened a new era of self-government in India. So much is evident to all who have eyes to see, even though they do not possess that life-long personal knowledge of Indian affairs which is regarded by many as the sole qualification for opinions on a series of problems which are founded on religious and racial divergencies, complicated by historical and financial associations, and aggravated by fundamental differences in estimating the responsibilities of more advanced civilisations towards those less fortunately situated. The existence of irreconcilables on all sides makes the future dark enough even to the experts. But it may be noted that Sir WILLIAM VINCENT, in the last sitting of which we have any detailed report, while regarding Dominion Home Rule as impracticable within the short period demanded by Noncoöperation, showed that the powers of the present Assembly are very large, and offer, indeed, ample scope to those who desire to do practical service for the country. Certain it is that within the constitution a vast field has been opened up for public health effort, and alone among the public services medicine has always and everywhere been common ground for men and women of opposing political camps. The opportunities of medicine in India are boundless, and those who are familiar only with the problems of preventable disease, as presented in the Mother Country and its self-governing dominions, are appalled when they are first brought face to face with the abysmal ignorance of the hygiene of life in the East; the quiet acceptance on the part of the people and of their rulers of preventable disease in every form passes understanding.

We have for some years given space to the reports of executive health officers in India, and have marvelled sometimes at the little interest which these amazing records have excited at home. But this apathy is passing away. For many reasons India is rapidly coming nearer, and the introductory remarks of Dr. J. E. SANDILANDS (on p. 783) to his first report from Bombay will not fail to receive attention. The conditions of public health during the year, he says, were not satisfactory. They certainly were not, and we should like to see his report published in parallel columns with his last report as medical officer of health for the Royal Borough of Kensington. The public health officer in India will be aided in his survey by the decennial census taken on the night of March 18th, a quality of assistance which his colleague in Ireland may shortly be without, and we are glad to see the *Times of India* pointing out that all large plans for the benefit of the people have to be based upon accurate statistical information. India has something like one-fifth of the population of the world: the Bombay Presidency alone has some 20 million inhabitants distributed among more than 28,000 towns and villages. To deal with such multitudes will need the utmost coöperation in medical effort, and this feeling is brought out in a remarkable leading article in the *Indian Medical Gazette* of February forecasting the possibilities of the year 1921. It is unfortunate that from inevitable circumstances the medical men of India have become divided into a number of separate classes, but it is certain that a rearrangement of service will sooner or later occur, whereby India will receive, in the task of improving the physical and moral status of its heterogeneous population and of upbuilding native activities to that end, the full support which can only come from conjoint design.

The forces of division are becoming from year to year less straitly divided. Both the Army and the Indian Medical Service are increasingly interested in civilian health problems. It is still fresh in the memory how the R.A.M.C. in Flanders, and even in England during the war years, was compelled to safeguard the soldier against ill-health in the community among which he was living. A similar tendency is at work in India. At the same time the Women's Medical Service grows, and from year to year the output of the Indian medical schools recognised by the General Medical Council is larger. The difficulty in obtaining sufficient obstetric experience will not prove insurmountable. Natives of India in increasing numbers come over to this country for part or the whole of their medical study. An article by Dr. CECIL WEBB-JOHNSON in the current issue of the *Asiatic Review* gives voice to the confidence felt in the future by some. Indian medical men, he writes, educated in Europe and conversant with all the latest scientific knowledge, will be the custodians of their country's health, and he pictures them working without jealousy side by side with the Aryan colleagues whose methods they have adopted. True it is that the Esher and Lovett Committees have not solved the obvious difficulties in the way, but these difficulties have been stated and faced; that is a great gain. There will be heavy sacrifices to be made, and more than one fine ideal will not materialise along projected lines. But such disappointments are the everlasting comrades of big changes, while everything good that we can expect from the future will be based on the splendid work of the past. That credit can never be taken from the old order, even though it may have to give place to the new.

◆

The Physiology of Pain.

KNOWLEDGE of the sensory, affective aspect of mind has not advanced so far as that of the motor aspect. In the main this has been due to the greater complexity of the physical apparatus, corresponding to the greater rôle played in our life by the affective side of our nature. One result of this comparative neglect has been that the "mystery of pain" has remained even into our time a mystery. Meeting us at every turn, in ourselves or in others, we yet remain in ignorance of its mechanism and significance. The moralists would have us believe that pain exists for the finer tempering of our souls; the physiologists, unconsciously influenced by the moralists it almost would appear, have defined pain as "a physical adjunct to a protective reflex." Such a definition cannot satisfy us, for it is clear that much of the pain which we suffer in no way acts as a protection or warning, while we meet many conditions in which pain does not occur until they have reached a stage when they are irremediable.

In the April number of *Medical Science Abstracts and Reviews*, Mr. WILFRED TROTTER reviews the evidence, experimental and otherwise, of the last 15 years, and as a biologist reaches the conclusion that sensibility to pain is the survival in us of the primordial mode of sensation. The known facts of the normal mechanism of pain warrant the statement "that the peripheral pain mechanism is excitable by a number of different stimuli which have no single physical character in common, that while it requires a stimulus relatively intense, it yields a reaction relatively excessive, and that its characteristic anatomical feature differs strongly from all other so-called end-organs in being a mere free and naked terminal arborisation." Pain differs from all other sensations in its urgency and unpleasant affective tone; other sensations, as it were, flow quietly and smoothly into the sensorium, the mind is capable of discrimination between them and their degrees; pain bursts suddenly upon the sensorium, liberating a veritable explosion of reactive energy. The study of experimental nerve section in man has shown that during recovery all sensations tend to show intensification; this has been interpreted as a defect phenomenon by HEAD, but TROTTER holds that the pathological process must be considered as a causative factor in its production, the essential part of the process being contact between the nerve fibrils and the somatic tissues. He directs attention to the thoroughness with which nervous tissue is normally insulated from the somatic tissues, the dura acting as insulator for the brain and spinal cord, the neurilemma for the finest nerve twigs; even the blood-vessels supplying the central nervous system are carefully separated from the nervous tisue by the so-called perivascular lymphatics. The only parts of the system normally in intimate contact with the somatic tissues are the free naked arborisations which subserve pain; other sensory nerve-endings are various in form, but all have one characteristic in common, they are shut in by a well-marked encapsulating formation. Further, in the case of amputation the nerve fibres are brought into intimate contact with the somatic tissues, and it is well known that the element of pain is added to the other sensations constituting the phantom limb.

It is suggested that the pain nerve is constantly exposed to a mild subliminal excitation and that the secret of the peculiarities of the pain sensation lies in the fact that the nerve by which it is originated is a nerve differing from all other nerves in being normally in a state of continuous excitation. The completeness of the insulation would appear to be a means of damping down sensation and thus rendering deliberation and discrimination possible. Animals with a diffuse nervous system respond to stimulation immediately and urgently, and we may suppose their sensations to have the quality which survives in us only as pain. In man any break in the insulation, by bringing into play the hostility between neural and non-neural tissues, throws back all forms of sensibility more or less into the primitive type, and this explains why pain is the commonest of symptoms, and why it is so apt to become inveterate.

GUY'S HOSPITAL: DENTAL RESEARCH FELLOWSHIP FUND.—This Fund consists of a sum of money not exceeding £300 per annum, to be awarded wholly or in part for dental research. Applicants, whether graduates or undergraduates, must have studied in the Medical or Dental School of Guy's Hospital, unless the Advisory Body decides that the circumstances are exceptional. Holders of grants from the Fund may, at the discretion of the Advisory Body, be part-time research workers. All research work undertaken with the aid of the Fund must be carried out entirely in Guy's Hospital or the schools attached thereto, unless the Advisory Body agrees that some portion of the study might with advantage be pursued elsewhere. Applications for grants should be made to the Clinical Research Committee of Guy's Hospital, London Bridge, S.E. 1.

Annotations.

"Ne quid nimis."

DR. ADDISON.

THE retirement of Dr. Addison from the Ministry of Health forms a fitting opportunity to indicate what has been done under his rule, both because recognition is due to him for a large amount of pioneer and difficult work, and because in this way we shall see what is the legacy of responsibility left to his successor, Sir Alfred Mond. The Ministry of Health came into existence in June, 1919, in deference to a very general feeling of all classes and political schools of thought that the health of the people was of sufficient importance to demand for its care a first-class Government Department. In the beginning the labours of the Ministry were largely directed towards the amalgamation and rearrangement of scattered duties previously discharged by six or seven separate bureaux, the majority of those duties having been the work of the Local Government Board and the National Insurance Commissions. To continue the activities thus indicated, and abolish overlapping while securing practical results, would have been a large task in itself, even had we as a nation been enjoying the peace and prosperity of pre-war days. But just as to some extent the lessons of the war led at length to the establishment of a Ministry whose creation had been talked of for half a generation, so the results of the war gave that Ministry, when created, a programme of extraordinary arduousness. Not only were there endless things to do, but they all had to be done in the face of unusual obstacles. Under Dr. Addison the course for the future has been in many directions made secure. The housing question, which lies at the back of preventive medicine, has been tackled; it is true that only a commencement has been made, but the national needs have been estimated and the local responsibility to meet those needs indicated. The many problems epitomised in the phrase "the hospital question" have been under discussions in which officials and medical men, philanthropists and men of business, have taken part with the Government, and the result has been the throwing of much light upon the position of the voluntary hospitals, so that practical steps were initiated to assist them in their beneficence. On many subjects of public health wise advice has been published by the Ministry, and throughout these publications, as well as in the activities already mentioned, a non-political attitude has been maintained, though that fact has not protected the Ministry from considerable political attack. Dr. Addison has had to discharge difficult and thankless duties, and his inventiveness and wide sympathies have been an asset to the country. To have been the first Minister of Health must remain for him an abiding source of legitimate pride.

ROYAL ARMY MEDICAL CORPS WAR MEMORIAL.

IN the war no unit played a grander part than the Royal Army Medical Corps, the greater proportion of which, in a short time after the catastrophic beginning, consisted of civilian officers. The way in which the Corps met and discharged its responsibilities requires no praise from us—it has received universal praise. Early in 1919, when the closing episodes of the great conflict were in progress, a scheme was put forward for the erection of a memorial to the officers and men of all branches of the Corps who had been killed in action or who had otherwise laid down their lives. For this purpose a comprehensive committee was formed consisting of representatives of the Regular, Territorial, Special Reserve, and Temporary Officers, as well as of non-commissioned officers and distinguished physicians and surgeons, consultants to the Corps. This committee made tentative proposals with respect to the form which the memorial should take, and these have since been the subject of consideration by a subcommittee. A definite scheme has now emerged, and was laid before a meeting of the General Committee held a few weeks ago. Roughly speaking, the sum of £19,000 has been collected, and of this amount about £1500 has been ear-marked by donors for families and dependents of the fallen. This money will be allocated for administration to the R.A.M.C. Regular and Auxiliary Funds in proportions still to be determined.

There remains a sum of nearly £18,000, and much anxious thought has been spent on its disposal. The Chairman, Sir Alfred Keogh, explained to the committee that the inevitable suggestions of memorials in stone, of scholarships and gold medals, had been considered and eventually discarded in favour of a scheme which he described as beautiful, essentially national, and almost without precedent. This proposal, emanating from Colonel C. R. Tyrrell, the acting secretary, envisaged the erection of a tablet in Westminster Abbey, near to the grave of the Unknown Warrior, commemorating the dead, and the inscription of their names in a Golden Book to be kept in the Chapter House. This scheme would allow of handing over a considerable sum of money towards the restoration of the Abbey, and the chairman appeared to interpret the feeling of the committee when he said that this gift alone would form a most fitting memorial. Sir Norman Moore, Sir Arthur Sloggett, Sir Launcelotte Gubbins, and Sir W. G. Macpherson spoke in favour of the suggestion; the President of the Royal College of Surgeons of England had previously expressed his approval, while representatives of non-commissioned officers present at the committee gave enthusiastic support. Eventually a resolution was passed approving the allocation of a sum not exceeding £10,000 to the Abbey Restoration Fund; of the erection of a tablet in the Abbey, with replicas in Edinburgh and in Dublin; of a distribution of photographs of the tablet and of plans showing its position in the Abbey to relatives of those who had lost their lives. A small executive committee consisting of Sir John Goodwin, Sir Norman Moore, Sir W. G. Macpherson, Sir L. Gubbins, Colonel Tyrrell and Major E. B. Waggett (joint secretaries), and Sergeant-Major Walton was elected to consider the appointment of a Custodian of the Book, the wording on the tablet, and other details.

TEA INTOXICATION.

Dr. M. Allen Starr,[1] of New York, remarks that, though acute cases of tea poisoning are extremely rare, subacute and chronic cases are not uncommon and are liable to escape recognition. He reports the case of three members of a college football team who were brought to him by their captain on the suspicion of poisoning by strychnine in a tonic ordered by the medical man who belonged to a rival college—the same being a cheery view of the results of athletic rivalry. The rapid pulse, increased knee-jerks, and excessive irritation of the nervous system rendered the idea of strychnine poisoning plausible, but this supposition was negatived by inspection of the prescription of the tonic, which contained only 1/60 gr. of strychnine, as well as by the high character of the physician. Further investigation showed that the trainer had been in the habit of giving the team large doses of tea, each member drinking at least two quarts a day. The three men in question had apparently been less tolerant than the rest, but all their symptoms disappeared when the tea was withdrawn. Dr. Starr also relates a case of chronic tea poisoning in a tea taster from Japan, who had been in the habit of tasting about a hundred samples of tea a day. The patient gradually developed a condition of extreme restlessness, nervousness, mental depression, and insomnia, with tremor of the hands, attacks of headache, vertigo, and palpitation. It was not until he had had three months' rest and hydrotherapeutic treatment that he finally recovered. Dr. Starr further alludes to the prevalence of chronic tea intoxication described by James Wood in 1912 among Irish servant girls in Brooklyn, in many of whom the diagnosis of the cause had been overlooked and the treatment had been directed to indigestion or general nervousness without result.

LIVERPOOL PORT ADMINISTRATION.

FOR many reasons a special responsibility rests just now upon the sanitary authorities of our ports, if only on account of the great volume of emigration and transmigration. Some public anxiety may therefore have been created by certain widely-circulated strictures on the Liverpool port administration. We learn, however, that nothing is known by the Port Sanitary Department at Liverpool of the visit of Dr. Emile Nadeau, nor can it be ascertained that he visited representatives either of the Mersey Docks and Harbour Board, H.M. Customs, Ministry of Health, nor the Immigration Officer. If Dr. Nadeau had represented the Canadian Government as has been stated, it is improbable that he would have made strictures through the press and have left the port without communicating in any way whatever with any responsible authority. By a coincidence the U.S. Commissioner for Immigration visited Liverpool during the same week and expressed himself as greatly pleased with the arrangements made to deal with the transmigrants to the United States. As a matter of fact, an attempt is being made, with the coöperation of all interested parties, to perfect the arrangements for the inspection of aliens coming into this country, although difficulties stand in the way of extensive structural alteration.

EGYPTIAN OPHTHALMIC HOSPITALS.

THE seventh annual report[1] of the Director of Ophthalmic Hospitals follows the lines of those published in previous years. The number of ophthalmic hospitals which have been established in the country districts of Egypt since Sir Ernest Cassel made his gift of £40,000 in 1903 is 18, including four travelling camps under canvas. The principal diseases with which they have to deal are, on the one hand, trachoma, and, on the other hand, contagious ophthalmia due to various infective micro-organisms. With regard to trachoma, its incidence in the schools has been diminished, in its active or serious stage, from 62 per cent. when systematic treatment began to 8 per cent. Contagious ophthalmia, and especially that due to the gonococcus, is responsible for by far the greater part of the blindness that exists, but it is to be noted that the gonococcus has not a venereal origin in Egypt, but is transferred from eye to eye, mainly by fingers, garments, and towels. The part played by flies in the transmission of bacterial eye infections is the subject of investigations now in progress. Gonococcal ophthalmia, on the whole, seems to be a milder affection than it is in this country, and the suggestion is made that in Egypt the strain of gonococcus may be less virulent, or even that it may not be the gonococcus at all as we know it in Europe but another morphologically similar organism. The study of the incidence of the different forms of contagious ophthalmia in relation to the temperature of the air, which has formed a feature in previous annual reports, is continued in this.

OCULAR PALSIES.

THE debate on ocular palsies at the joint meeting of the Ophthalmological and Neurological Sections of the Royal Society of Medicine (see p. 748) served to bring into prominence both the immensity of the subject and the variety of point of view. If, as is often the case, an ocular paralysis is the earliest, or for a time the sole, symptom of incipient nervous disease, it is natural that the ophthalmologist should be consulted; but it is desirable that he should be conversant with, or at least able to recognise those nervous affections of which ocular palsies may be the expression. In tabes dorsalis, disseminated sclerosis, myasthenia gravis, encephalitis in one or other form, in ventricular tumours, motor neuron disease, and a host of other intracranial conditions, an ocular palsy may be the first symptom to attract attention, so that the practical value for the ophthalmologist of a discussion of the subject by the neurologist must be considerable. This ætiological multiplicity, of course, increases the difficulty of reaching an accurate diagnosis at an early period, and when the clinician is confronted by monosymptomatic cases he may be unable to come to a definite conclusion; even throughout the whole course of a recovering case diagnosis may never pass the provisional stage. There can be little doubt that absence of pathological examination creates a lacuna in not a few instances which nothing else can fill, and although present-day fashion rather decries morbid anatomy, the relative paucity of pathological knowledge in such conditions as recurrent ocular palsies, ophthalmoplegic migraine, and the ophthalmoplegias of Graves's disease—to mention but one or two—is certainly to be regretted. Accuracy in prognosis being the desideratum, any advance even in morphological pathology is to be welcomed, for more than one speaker at the discussion was forced to admit the purely speculative nature of the explanation offered for this or that clinical condition. Wide as was the ground covered, there were still certain aspects of the subject ignored or scarcely touched. Something more, for example, might have been said of the occurrence of ocular paralysis in ordinary hemiplegia, on the same side as the latter, and on the curious fact of its being much less common in adult than in infantile cases. Dissociation of bilaterally acting muscular couples by a cerebral hemiplegia is a point of some physiological interest, which, along with a similar dissociation not infrequently seen in Jacksonian epilepsy, suggests the desirability of some modification of the long-accepted Broadbent's law. Allusion was made by one speaker to the apparent "unwillingness" of some patients with cerebellar disease to direct their gaze in a particular direction, a phenomenon of some importance which is, perhaps, but part of a wider physiological disturbance. Years ago Hughlings Jackson recorded the case of a patient in whom an examination of the eyes was altogether impracticable; "he made efforts, but he never did what I told him, whether it was to look in a particular way or to keep his eyes still. He could not be got to look in any particular direction, although he seemed on the alert to act and was all the time doing something with his muscles." This apraxia of the ocular muscles is on a par with other apraxic disorders, though there may be difficulty in distinguishing an apraxia from a psychical aboulia on the one hand, or from some motor defects of a lower level on the other. A further defect to which allusion may be made is that in which the patient is unable to turn his eyes conjugately to one or other side, but if he is asked to fixate on an object in front of him, and his head be then passively turned to one side, his eyes, remaining fixed on the object, are found to be occupying that lateral position which they cannot assume voluntarily. Occasionally a patient is seen who cannot keep his eyes closed to order, an "Apraxie des Lidschlüsses" also worthy of some attention. The whole topic of ocular "palsies" beyond the middle level deserves careful clinical study.

---

BENCE-JONES PROTEINURIA.

Dr. Waltman Walters, Fellow in Medicine of the Mayo Foundation, who reports[1] three cases, states that this condition was first described by Bence-Jones in 1847, who found a peculiar form of protein in the urine in a case of osteomalacia. Only two other cases were recorded between 1847 and 1889, by Kühne and Kahler respectively, but Rosenbloom collected 205 examples from the literature between 1889 and 1917, the great majority being in cases of multiple myeloma. The other diseases in which Bence-Jones proteinuria have been found are lymphatic leukæmia, myeloid leukæmia, myxœdema, exophthalmic goitre, carcinomatosis, nephritis, hypertension, and experimental poisoning by pyrodin. Of Dr. Walters's cases one had generalised carcinomatosis, one multiple myeloma, and in one the diagnosis was obscure. The most characteristic reactions of Bence-Jones protein are its precipitation from acid urine at temperatures of from 55° to 60° C., its disappearance at the boiling point with the formation of a clear solution, and its reappearance as the solution cools. When concentrated nitric acid or hydrochloric acid is added to urine containing Bence-Jones protein the latter is precipitated in a dense white cloud, which becomes dissolved as the temperature is raised to boiling point and reappears as the urine is cooled. As regards the origin of the protein Dr. Walters is in favour of the hypothesis of Hopkins and Savory, according to which it represents either normal, abnormal, or aberrant stages of bone synthesis, the completion of which is hindered by indeterminate pathological conditions. Dr. Walters conducted metabolic studies on each of his three patients to determine variations in excretion on various diets with the following results: (1) the quantity of Bence-Jones protein excreted was independent of the protein intake, as was shown by an approximately constant excretion for three periods irrespective of changes in diet; (2) the amount of Bence-Jones protein excreted during the night when food was not taken was only slightly less than the amount excreted during the day; (3) there was not a constant relationship between the quantity of Bence-Jones protein and the total urinary nitrogen excreted. As the presence of Bence-Jones protein in the urine led to detection in the blood, Dr. Walters suggests that possibly other proteins of a similar or dissimilar nature are in existence in the blood and are not excreted by the kidney.

ATMOSPHERIC CONDITIONS IN BOOT FACTORIES.[1]

THE introduction by Dr. Leonard Hill of the kata-thermometer has provided us with a much-needed means for testing the physiological efficiency of atmospheric conditions. The Industrial Fatigue Research Board, perceiving this, instituted an inquiry based upon the use of this instrument in boot and shoe factories, and have now published results which represent the first systematic attempt to investigate on a large scale the physiological state of persons exposed to particular conditions of ventilation. The writers of the report, Messrs. W. D. Hambly and T. Bedford, are to be congratulated on the way in which they have pursued this new line of investigation and have presented their observations. They accept the aim of ventilation physiologically to be to produce an atmosphere cool rather than hot, dry rather than damp, diverse in temperature rather than uniform and monotonous, and moving rather than still. The difficulties associated with estimating these desiderata, and the reservations which have to be made, are clearly stated. Evidence is steadily accumulating that a definite standard of rates of cooling, as measured by the kata-thermometer, may soon be fixed for a healthy atmosphere; certain tentative suggestions are now put forward which propose different temperatures and rates of cooling for different processes, a rate of cooling of 8 to 9 dry kata with a temperature of 55° to 60°F. being suggested for heavy work, and a rate of cooling of 6 to 7 dry kata with a temperature of 65° to 67°F. for sedentary work requiring delicate manipulation. The report is based on a large number of observations made in 35 factories during summer and winter. The data are excellently presented in the form of frequency curves, the exact meaning of which is neatly explained in an appendix; by this means the trend of the observations, which would be lost in a table of figures, can be seen at a glance. The best way of ventilating large rooms such as are found in modern factories is discussed with special reference to the methods found efficacious in aircraft doping rooms in which a high standard of air movement has to be maintained to carry off noxious vapour. The employment of suitable ventilating fans, as used in doping rooms, with adequate air inlets on the opposite side of the room, is advocated. Multi-story buildings were found rather easier to ventilate than single-story ones, and ventilation was usually found better in summer than in winter. Generally no particular attention was discovered to be paid to maintaining different rates of air movement and warmth according to the amount of physical exertion entailed by the work in progress. Sedentary work was being carried on in rooms too cold in winter and too hot in summer, and heavy manual work in rooms with unsatisfactory rates of cooling and temperatures in both seasons of the year. This report is the second of a series dealing with the boot and shoe industry, further additions to which are promised. It is a good piece of work, throwing valuable light on conditions of labour and on the way in which health and efficiency can be improved by attention to the human factor in industry.

---

BROMISM THROUGH MATERNAL MILK.

A CURIOUS case of bromism is reported from the pediatric department of the diagnostic clinic of the State Department of Health at Carthage, New York.[1] A breast-fed infant of 6 months presented an apparently painful papulo-pustular eruption. There was a history of a general "white" rash at birth, followed by the appearance of this papulo-pustular eruption at the age of 6 weeks. The diagnosis of bromism was made and was confirmed by the discovery of bromine in the mother's milk. The origin of the bromine was not far to seek. The mother, a nervous individual, had been taking for two years a proprietary remedy called Miles' Restorative Nervine, shown by the American Medical Association to contain bromides of ammonium, potassium, and sodium, along with chloride and benzoate of sodium. No record has been found in the literature of bromism acquired in this way, though it is noted that some American authors have observed the secretion of bromides in human milk. This is mentioned also in Hale White's "Materia Medica," but we have found no allusion in accessible medical literature to the danger of producing bromism in the infant from administering bromides to the nursing mother.

FILIPPO RHO.

As we have already mentioned, Professor Filippo Rho, "Medical Lieutenant-General of the Royal Italian Navy," its medical Director-General during the war, retired last September after 40 years of distinguished service. The *Annali di Medicina Navale* for December expresses the respect in which he was held in the department and the regret felt at his retirement, which is technically due to the reduction of the Naval Medical Service by the abolition of his, its highest, rank. Professor Rho joined the Italian Navy in 1880, and in the following year joined a ship, which took him round the world, as her zoologist. He early took up the study of tropical diseases, and was for ten years demonstrator of tropical disease at the University of Naples, where he, with others, built up a Post-graduate School of Naval and Colonial Medicine, and also established the *Annali*, which budded off from the *Italian Medical Journal* in 1895. His was the foresight that, for the Italian Navy, decided in 1898 that there should be in action not one dressing-station but two, and planned the medical equipment of ships accordingly; he also took an early share in the establishment of hospital ships. In January, 1912, he maintained the need for anti-typhoid inoculation and later for Castellani's triple vaccine (T.A.B.). In 1913 he secured that Metchnikoff's calomel ointment should be used in the navy prophylactically, and the practice spread to the army. It is also claimed that owing to his initiative and his methods it was that the naval brigade on the lower Piave in 1918 suffered far less from malaria than did the army generally, and he took a forward part in Italy, as the war advanced, in finding out how to feed the army with equal calories at less expense. He maintained that Rubner's allowance of meat in his diet for heavy labour was excessive, and got the soldiers' diet in Italy altered accordingly. That alteration certainly assisted Italy to remain in the war. He published his book on tropical diseases in 1897. He has a long record of original work, and leaves the service followed by the regrets of all his brother officers and the respect of everyone who is acquainted with his original investigations.

RESEARCH SCHOLARSHIPS AND GRANTS OF THE BRITISH MEDICAL ASSOCIATION.

THE Council of the British Medical Association is prepared to receive applications for research scholarships as follows:—

1. An *Ernest Hart Memorial Scholarship*, of the value of £200 per annum, for the study of some subject in the department of State medicine.
2. *Three Research Scholarships*, each of the value of £150 per annum, for research into some subject relating to the causation, prevention, or treatment of disease.

Each scholarship is tenable for one year, commencing on Oct. 1st next. A scholar may be reappointed for not more than two additional terms. The Council of the Association is also prepared to receive applications for grants for the assistance of research. Preference will be given, other things being equal, to members of the medical profession, and to applicants who propose as subjects of investigation problems directly related to practical medicine.

Applications for scholarships and grants for the year 1921–22 must be made not later than Saturday, June 25th. Each application should be accompanied by testimonials, including a recommendation from the head of the laboratory, if any, in which the applicant proposes to work, setting out the fitness of the candidate to conduct such work, and the probable value of the work to be undertaken. This is not intended, however, to prevent applications for grants in aid of work which need not be performed in a recognised laboratory. The conditions of award and application forms will be supplied on application to the Medical Secretary of the Association, 429, Strand, London, W.C. 2.

WAR RISK INSURANCE IN U.S.A.

IN the *Military Surgeon* for February Surgeon J. G. Townsend, of the U.S. Public Health Service, tells how the War Risk Insurance of the United States is taking care of those disabled by the war. Every officer, man, or nurse, injured, or with disease contracted on duty, if insured against damage, has a claim against this insurance on account of the disability. Total and permanent disability receives some £240 a year, temporary total disability about £200; 50 per cent. and so on disabilities receive in proportion. In addition the U.S. gives a further compensation quite independently of the insurance; this latter compensation is not discussed in the article under notice. The examination and treatment of the ex-Service man has been turned over to the capable and ready hands of the valuable U.S. Public Health Service. Over 4,000,000 people have been discharged, all of whom are possible clients, and of them half a million have filed claims. The United States has been divided into 14 districts, each with a commissioned officer of the Public Health Service as district supervisor. He and his office hunt up and keep record of the disabled in the district, gather them in for examination, sending passage warrants, meal vouchers, &c.; patients with tuberculosis, if summoned, are sent packets with paper spittoons and paper napkins; doctors are appointed in large towns and at important railway junctions to examine the disabled and furnish reports, which are kept filed, each patient's dossier by itself; a pathological index of all cases in the district is kept up to date, so that the number of any sort in the district can be stated at any time; also there is an office personnel to deal with pay and leave, and an accounts section. 30,000 claims are examined monthly, and between 5 and 6 million dollars paid out every month in insurance. Disabilities are still developing, the tuberculosis maximum is expected in 1923, the mental and psychical in 1926. Of 3500 amputation cases, 11 had lost both arms, 68 both legs. Double total permanent disabilities such as these mentioned, or eyes, get £500 a year. Of 82,000 hospital cases, 19,000 were tuberculous (23 per cent.).

EXPECTED AND ACTUAL MORTALITY.

THE Prudential Assurance Company recently published curves showing the actual mortality amongst its industrial branch policy-holders compared with the expected mortality of the population as a whole. The two lines run approximately close to each other except during the war years, when the mortality curve leaps up to tragic heights. In fact, the line of deaths experienced falls below the line of expected mortality. It is obvious that the further below the expected line the line of actual mortality falls, the more profitable it is for the company and the more profitable to the public could the terms of assurance become. The bonus would be greater or the premiums could be more favourable. There are two factors tending the one to pull the line upwards, the other to pull it downwards: these are adverse selection, conscious or unconscious, on the part of the public and the favourable selection afforded by medical examination. Let us examine these factors to see what they mean and how they work out in actual practice. By adverse selection is meant this: if a man knows or suspects himself to be a poor life he will naturally choose the table which gives him the greatest return for the least possible outlay; not expecting to reach the full span he will not pay the higher premiums of an endowment policy, but will choose a whole-life table or some long-dated assurance with its smaller premium. If three representative tables are taken from the ordinary branch of this Company, and the ratio of actual to expected deaths amongst healthy males noted, some interesting comparative figures will be obtained. The three tables taken for comparison are: A, an endowment table with medical examination; B, a 10 years table without medical examination; C, a whole-life table with medical examination. It will be seen that adverse selection militates against B and C. Against B because there is no medical examination, and against C because it is a whole-life table with low premiums. The unfavourable factor in this last group, however, should be eliminated or controlled by medical examination. Taking the actual mortality experienced in the first four years and comparing this with the expected mortality in this same period amongst unselected healthy males the result can be represented approximately by the following figures: if the result for Table A is represented by the figure 100, that for B will be 152 and for C 167. That is to say, the most unfavourable mortality is experienced in the whole-life table. Medical examination has not eliminated and only very imperfectly controlled the adverse selection. If we analyse the causes of death, it is found that a large proportion of early claims are due to deaths from pulmonary tuberculosis or from cardio-vascular conditions, apoplexy, uræmia, and other results of arteriosclerosis or chronic Bright's disease. To eliminate the first of these causes is admittedly difficult, but the early claims resulting from the others could be very largely reduced if blood-pressure estimation and interpretation and methods for estimating myocardial efficiency were more widely known and employed.

FOOD AND THE PEOPLE.

THE business of obtaining food is the most important one in which man is engaged. The fear of starvation may be the ultimate reason for the non-acceptance by miners of a lower rate of wages when Government control ceased on March 31st. If that is the case and they are not reassured the struggle must needs be a bitter one, for the social instinct to provide for wife and child is stronger than most other motives. The economist ought to tell us whether such a fear is justified by the industrial outlook, and he cannot do so for the number of x's in the economic equation. One of these unknowns is a proper standard of nutrition, and it is a tragic coincidence that the Ministry of Food, which was at one time assisted by a committee of the Royal Society to fulfil this task, was wound up on the fateful day when its guidance again became imperative. As scientific adviser to the Ministry, Professor E. H. Starling solemnly warned us two years ago against demobilising the official Food Department without creating a board of human and animal nutrition to continue for the public benefit the scientific work which grew up during the war at the Ministry of Food. And here we are with, as far as we know, the only surviving asset, the satisfaction of getting a full pound of tea without the packing paper being included in the weight. But it is hardly exaggeration to state that nutrition became almost an exact science during the existence of the Ministry. Long before the war, of course, Voit and Chittenden had demonstrated that good mental and physical work required a certain level of protein in the diet, but their figures differed so widely as to make reconcilement difficult, and the civilised world measured its food requirements, like the savage, by the comfortable sense of abdominal tension. The need for strict rationing, international and national, brought home elementary dietetic principles to all ranks of society, and particularly to those at the two extremes who needed it most. Stimulated by the Eltzbacher report in Germany, the Food Committee of the Royal Society drew up in 1916 a report on the Food-supply of the United Kingdom, and the late Sir William Thompson did a similar service for Ireland; more complete knowledge led to the issue in March, 1919, of a report on the Food Requirements of Man, including their variations according to age, sex, size, and occupation, which placed on a secure basis the quantitative aspect of the national food-supply as determined under conditions of sufficiency, if not exactly of plenty. The study of a scanty diet, which begins with Sir James McGrigor's prejudiced survey of prison diet in 1823, is now being continued with benevolent intent in several parts of the continent. Applying the Rohrer formula of weight to height, 70 per cent. of German children are found to be undernourished by the American Friends' Service Committee, and are to receive a supplementary daily meal. Thus the pre-war plenty, the war sufficiency, and the post-war scarcity are providing material for a scientific analysis of the quantitative needs of the human body, which no Government that has to deal with economic questions can afford to ignore. It might have been assumed that the Ministry of Health was collecting and codifying this material for use both in Government counsels and for popular education had not Dr. Addison specifically disclaimed in the House of Commons the need for the issue of such food lore. We regard the action of the German Health Department as well-advised in the issue of a manifesto on accessory food substances. For with the growing realisation of their place in the bodily economy much of the older teaching, based on mere food value, will go overboard. And it is the function of a Ministry of Health to instruct the people in the right conduct of the common everyday things of life.

Viscount Astor's resignation as Parliamentary Secretary to the Ministry of Health leaves the position open for the appointment of a medical man.

THE Oliver Sharpey lectures will be delivered at the Royal College of Physicians of London on April 12th and 14th at 5 P.M. by Dr. Thomas Lewis, the title being "Observations upon the Nature of Auricular Flutter and Fibrillation."

AT the next election to the Council of the Royal College of Surgeons of England, which will take place on Thursday, July 7th, there will be four vacancies, and the following 11 candidates will submit themselves to the vote of the Fellows: Mr. H. J. Waring, Mr. F. F. Burghard, Mr. W. Thelwall Thomas, Mr. A. H. Cheatle, Mr. J. H. Fisher, Mr. William Turner, Mr. C. H. Fagge, Mr. Victor Bonney, Mr. L. Bathe Rawling, Mr. Donald J. Armour, and Mr. Russell J. Howard. Mr. Waring and Mr. Burghard are retiring by rotation and offering themselves for re-election.

A DEFENCE OF THE MINISTRY OF HEALTH:

DR. ADDISON'S SPEECH AT EXETER.

SPEAKING at a dinner given by the Mayor of Exeter (Dr. A. C. Roper) on March 30th, Dr. Addison, Minister of Health, said the man who deserted a professional career and entered upon the uncertain path of a political life was rather looked upon as a suspect by the average professional man. He was glad that, at all events, the citizens of Exeter had recognised that medical men in their city council could, and ought to, render service. And what was true of the city of Exeter, he thought, ought to be true in the councils of the State.

Outlook of Medical Men on Public Affairs.

It always seemed to him to be a singular drawback to their profession that, immersed as most of them were in attendance upon the individual, they were apt to overlook, or perhaps they had not time to think about, the community of which that individual formed but a single part. They did not require to think far before recognising things which, as professional men, they knew should and could be done, but only by some measure of collective action of instruments of government. He believed that the suspicion with which a good many medical men regarded the medical politician existed only because their profession was so interesting and their work so absorbing that they had neither the time nor the disposition to study health questions from the State point of view. Whether or not that was the explanation, he recognised the fact and endured it with all the fortitude he could. While there had grown up in this country a collection of responsibilities, powers, and duties, scattered about through various departments of the State, concerned more or less with promotion, preservation, or protection of the life and health of the individual citizen, they had never been brought together as far as was possible, organised collectively, and directed as one.

First Efforts of the Ministry of Health.

The Ministry had not yet been at work very long; it had had a good many teething troubles, and was not without its critics, especially in certain sections of the press, which were perhaps sometimes more interested in the ventilation of a personal grudge than in the statement or consideration of the facts of the case on their merits; and so it came about that there were many things which had never been stated or even understood. In the first place, he thought that the motive of the Government organisation and development of the health services of the State ought to be increase of the value and efficiency of those services for the prevention of sickness and disease.

Housing.

No subject undertaken at the Ministry of Health had brought them more ridicule than that of housing; but he put housing first as a preventive health service. A start had been made, and they at least knew where they were going. For the first time a duty had been cast—and he did not apologise for its being a duty—upon local authorities to make a return as to what were the needs of the community in terms of houses. According to the 1911 standard two million people were said to be living under insanitary conditions. He wanted to alter that standard; it was useless to talk of stamping out tubercle when so many people were compelled to live in houses condemned as unfit for human habitation. It might well be that it would take 20 years to get the rehousing of this country on a well-established basis: but that was a matter of no consequence. What mattered was that they had obtained a minimum standard, based upon the health requirements of the people for two-thirds of the hours they lived. This measure was more essential, he believed, to improving the health and well-being of the child and other population than any other that could have been taken up. The Ministry had been beset with all manner of difficulties, but they had ploughed their way through some of them; the rest would be overcome in time. Soon they would be coming to the second stage—the allocation to every city and town within the limits of finance available a sum to help in dealing with the insanitary dwellings in their midst, and he believed the views of the medical profession thereupon would be unanimous.

Medical Advice in Public Policy.

Proceeding, Dr. Addison said there could be no doubt that the medical profession would more and more be forced into public affairs by public opinion and the spread of education. It was one of the first requirements of their profession that there should be central and local bodies of men accustomed to meet together and discuss public questions in which professional knowledge or interests were concerned, so that considered professional advice might be available when required. Public bodies and the State also, he thought, had often gone wrong, or missed an opportunity because of the lack of such guidance and advice; and he would repeat what he had already said in London a short time ago—a request to his professional brethren to get busy on this matter.

Passing on to the question of hospitals, Dr. Addison said the great masses of the people were needing more expeditious hospital treatment, and that the accommodation available for them in the voluntary institutions was at present insufficient. Side by side with this was the mass of empty accommodation, and it was impossible to think that they could go on for ever like that. There was the demand on one side and the supply on the other, but the two never met; and because the Ministry ventured to think a little in advance, they got into trouble; nevertheless, they were going on with it.

Cancer.—Tubercle.—Child Mortality.

Referring to the cancer problem, Dr. Addison said he should like to see a more comprehensive attempt made to tackle it. Looking at the results from such knowledge as could be gleaned, it did not seem to him that they were much further ahead as yet. The tale of death was still as great, if not greater, and he thought there was a great opportunity for a wise expenditure of money in the interests of economy. Statistics showed that in 1918 58,000 persons died of tuberculosis in this country, the previous lowest year being 1913, when there were 49,000 deaths. In 1919 the number fell to 46,000, and last year it dropped to 42,000. The cost of the whole tuberculosis service, taking the country as a whole, worked out at rather less than a penny rate in regard to local authorities, and a farthing out of every £ in regard to the Exchequer. With regard to infant mortality, the death-rate in London fell to 85 in 1919 and last year was down to 75. He understood it was still going down; but if the work was handled properly it could go down to 50.

Preventive Medicine.

In conclusion, Dr. Addison said that preventive medicine was the cheapest investment for the State. Well-considered and well-directed health efforts paid; and they were only just beginning to see it in this country, and as time went on the medical profession would be dragged further into those efforts. Therefore he had no manner of doubt that as on every other occasion which had called for their response they would rise to it easily in characteristic British fashion; the time was at hand and great would be their opportunity.

AT the Queen's Hall, Langham-place, London, Sir Arthur Conan Doyle will deliver next week three lectures entitled "Death and the Hereafter: the New Revelation." The first lecture, on Monday evening, April 11th, is termed "The Human Argument"; the second, on Tuesday evening, is termed "The Religious Argument"; and on Friday evening the Summary and General Conclusions will be delivered. The proceeds of the lectures, which will commence each evening at 8 o'clock, will be devoted to a special fund for the furtherance of spiritualistic work. Tickets for the lectures may be obtained at Queen's Hall box office and of the usual agents.

MEDICINE AND THE LAW.

The Defence of Warranty in Milk Prosecutions.

A CONFERENCE held at Battersea recently, at which 20 borough councils were represented, condemned in a plainly worded resolution what are known as the warranty provisions of the Food and Drugs Act as applied to the sale of milk. The resolution was to the effect that the section relating to warranty defences operates to the prejudice of the purchaser and the public health, and should be repealed. The section of the Sale of Food and Drugs Act referred to enables the seller of that which is not of the nature, substance, and quality of the article demanded, to prove in his defence that he himself bought it as being of the nature, substance, and quality demanded, and with a written warranty to that effect, and that he had no reason to believe it to be otherwise when he sold it, and that it was then in the same state as when he purchased it. He is then acquitted, but remains liable to pay the costs of the prosecution unless he has given notice to the prosecutor that he will rely upon the above defence. The effect of this defence in milk prosecutions has been what might have been expected, and particularly so since it has been held that there need not be a warranty given with each delivery of milk, but that it is enough to show by oral evidence that the particular consignment was purchased under a warranty intended to cover a series of consignments. At the conference referred to a case was mentioned in which Mr. Bankes, the magistrate, had said that he was bound to dismiss any charge before him, even though the milk sold was adulterated with 50 per cent. of water, if a warranty were proved to have been given to the defendant and the other conditions fulfilled.

The Question of Irresistible Impulse.

In the case of R. *v.* Quarmby, argued before the Court of Criminal Appeal, Mr. Justice Darling, Mr. Justice Avory, and Mr. Justice Sankey made it clear that the bench is not likely to allow any modification or alteration of the legal test of insanity when put forward as a defence to a prosecution. In the case in question counsel in effect asked the court to decide that an irresistible impulse urging a man to commit murder might be recognised as having induced him to do so, and as excusing him from responsibility for his act. Mr. Justice Darling, in the course of his judgment, said that Mr. Madden, counsel for the appellant, had complained that the judge had left to the jury the law of England as other judges had left it, and did not leave it to them to decide whether the prisoner acted from an irresistible impulse—whether it was not his subconscious rather than his conscious mind which was acting. If he had done so it would have been the first time it had been done by an English judge.

The Risks of a Neglected Cut.

At an inquest held recently at Bow on the body of a publican, 59 years of age, it was proved that the deceased had cut himself when shaving and had paid no attention to the wound beyond covering it with a piece of paper. Severe erysipelas had followed and the man had died. A verdict of accidental death followed, the coroner, Dr. R. L. Guthrie, observing that it might be a counsel of perfection to advise a man who cut himself with a razor to use an antiseptic immediately. It is not stated whether the paper used was a piece of the gummed edge of a sheet of postage stamps, but that certainly is regarded by many ignorant people as a convenient kind of "sticking plaster," regardless of either the original composition of the adherent or any subsequent impurity acquired. The postage stamp is less dangerous than the cobwebs which were used popularly for the stopping of bleeding before postage stamps were invented, and which are still employed in country districts, where barns and outbuildings make them easily obtainable. The knowledge that a wound of any kind should be kept as clean as possible is no doubt spreading, and deaths from such causes as the above are less common than formerly.

Need for Compulsory Cleanliness.

The necessity for revision of legislation dealing with cleanliness of the person was emphasised at a recent inquest held by Dr. F. J. Waldo, H.M. City Coroner, on a woman who died at Holloway Prison whilst undergoing a sentence of 14 days' imprisonment for being drunk and incapable. She had been found lying in a gutter, and when received into the prison was found to be in a very verminous condition and also to be suffering from scabies. Everything possible was done for her. The jury returned a verdict of death due to coma from blood-poisoning, following upon cellulitis of the neck caused by the bites of lice and from self-neglect, and the following unanimous rider was added:—

> "We are strongly of opinion that the Adoptive Act known as the Cleansing of the Persons Act, 1897, should be made compulsory, and that all local authorities should be called upon to provide cleansing and disinfection free of cost to all persons infested with vermin, and applying to the said authority for the cleansing of the person and clothing from vermin; further, we suggest that compulsory powers be given to the police to take any persons found in a public place, and visibly infested with vermin, to a local authority to be cleansed."

Dr. Waldo pointed out that vermin have been spread amongst children and others through verminous persons making use of seats intended for the public in such places as the Embankment and public parks, and also through merely lying on the ground. He pointed out that filth diseases, such as typhus and relapsing fever and trench fever, were spread by the agency of lice; the danger arising from these insects having been increased by the return home of soldiers and sailors. He personally did not at any time favour Adoptive Acts; in the past 10 years he had known of several deaths due directly to lice, and he had constantly advocated the conversion of the Cleansing Act into a compulsory measure. Persons like the deceased refused treatment when it was suggested by the police and others, and spread vermin broadcast in shelters and common lodging-houses, and sometimes even in prisons. When the Act was passed in 1897 he was medical officer of health at Southwark, and his local authority refused to adopt it on the score of expense. The Marylebone and St. Pancras authorities had first made use of the Act. He said that he would forward one copy of the rider to the Home Secretary and another to the London County Council.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

The Irish Census.

As was anticipated, the Government has recognised the futility of proceeding with an Irish Census in view of the opposition of a large proportion of the Irish people. An official statement has been issued to the effect that owing to the existence of a state of rebellion in the South and West of Ireland and the disturbed conditions in other parts of the country the Government, recognising that the returns of a Census would be incomplete or misleading, has decided to postpone the holding of a Census. It is further stated that under the Government of Ireland Act all responsibility in regard to the Census question passes to the Governments of Southern and Northern Ireland.

Asylums and the Deadlock.

The financial position of certain of the asylums of which the managing committees have declined to recognise the Local Government Board is rapidly reaching a crisis. For example, in Ballinasloe Asylum the officials and the great body of the attendants have been for the past two months without salaries or wages, and the present liability of the institution is £25,000. If the committee were willing to submit its books to Local Government Board audit the immediate advantage would be to secure the Government capitation grant, which originated under the Act of 1874, and was then fixed at 4*s.* a week, the principle adopted being that the Government should be responsible for half the cost of the inmates' maintenance. Under the Act of 1898 (Local

Government Act) the payment of these sums was transferred from the Consolidated Fund to the Irish Local Taxation Fund, which proved insufficient to pay the claims made upon it, and the asylum grant was accordingly reduced to 3*s*. 6*d*. per week per patient—a sum which, instead of paying half the cost, as originally intended, is now only a fourth of the cost of maintenance. Small as this sum may appear, in the case of Ballinasloe Asylum it amounted annually to £16,000. The anomaly in the case of the Ballinasloe Asylum is that while the committee refuses to recognise the Local Government Board, the Galway County Council, under which it works, recognises that Board.

Mental Disease in Ireland.

The annual report of the inspectors of lunatics for 1919 has recently been issued; it is founded upon official figures which in the near future, it seems, will not be forthcoming from any effective numbering of the people. The number of lunatics under care at the end of 1918 was 22,868 (males, 11,819; females, 11,049), and at the end of 1919 22,578 (males, 11,690; females, 10,888). The decrease in the total number of the insane under care, which has been going on since 1915, still continues, although at a reduced rate, the decrease in 1919 having been 290, as compared with 1025 in 1918. The total decrease during the five years from 1914 to 1919 amounted to 2602, or an average of 520 per annum. The last report referred to the fact that the reduction in the numbers was not due to any lessening of the admission rate in the district asylums, but to a heavy death-rate. The admission rate continues to increase, but the death-rate in these institutions, which amounted to 10·5 per cent. of the average number resident in 1917, and to 11·1 per cent. in 1918, fell to 9·3 per cent. in 1919. In spite of the decrease in recent years the number of the insane under care has increased from 268 per 100,000 of the average estimated population in the quinquennium 1880-84, to 546 per 100,000 in the quinquennium 1915-19. The total number of deaths was 1796, of which 9 were due to violence—viz., 2 from suicide, 5 from misadventure, and 2 from injuries inflicted by fellow-patients. In the previous year the number was 7—viz., 3 from suicide, 3 from misadventure, and 1 from injuries inflicted by a fellow-patient. One of the deaths from misadventure was from an unusual cause, the eating of yew leaves which had been distributed as "palm" on Palm Sunday.

Farewell Luncheon to the Medical Commissioner of Ministry of Pensions.

Medical men working in Ireland in connexion with the Ministry of Pensions feel much regret at the departure of Dr. D. A. Carruthers, who has been for two years Commissioner of Medical Services, and a luncheon was held on April 2nd at Mills's Restaurant, Dublin, attended by the members of the medical boards, by the medical referees, and the medical staff of the Ministry of Pensions in the Ireland (South) Region, to entertain him on the occasion of his departure from the Region. About 40 members of the medical profession engaged in the various branches of work in the Ministry of Pensions in the Region were present. Dr. C. R. Kilkelly (in the chair), Dr. F. E. Rainsford, Dr. H. B. Beatty, and Dr. R. J. Rowlette each voiced the esteem in which Dr. Carruthers was held by the various departments over whose work he has presided. A presentation and address subscribed by 70 medical men was made, and a further one on behalf of the clerical staff of the Medical Services Branch. Dr. Carruthers is succeeded in Ireland by Dr. H. S. Sugars, D.S.O.

Royal Victoria Hospital, Belfast.

The annual meeting of this institution was held on March 31st, Lady Pirrie, President of the hospital, being in the chair.

The medical report showed that 4270 intern patients had been treated during the year, an increase of 347 on the number for the previous year. Of the new cases admitted 2878 were surgical and 1099 medical. There were 2148 surgical operations performed in the wards, with 64 deaths after operation, giving a mortality of 2·98 per cent. The average stay of each patient in hospital was 25·4 days. In the extern department 30,236 new cases were treated during the year, as against 27,262 in 1919. The total attendances in this department numbered 90,708 (daily average 248); 418 surgical operations were performed in the extern theatre. Over 300 students received clinical instruction in the hospital during the year. The honorary treasurer, Mr. Henry Berrington, submitted the financial statement, which showed that the total revenue receipts from all sources during 1920 were £55,716 13*s*. 9*d*., an increase of £11,466 9*s*. 3*d*., as compared with the year 1919. The total revenue disbursements were £56,796 1*s*. 7*d*., an increase, as compared with 1919, of £11,466 9*s*. 3*d*. The cost per bed had risen from £65 in 1913 to £157 per bed in 1920. Mr. Berrington referred gratefully to the large increase in receipts. Lady Pirrie, in her presidential address, congratulated the hospital on its comparatively favourable financial position, and announced the receipt of two cheques which would more than wipe out the small adverse balance upon the year's working. She referred sympathetically to the retirement of the late superintendent, whilst giving a hearty welcome to his successor, Colonel J. V. Vincent. Colonel A. Fullerton, in submitting the medical and surgical report, dwelt on the great pressure upon the various departments of the hospital and on the need for further extensions. During the meeting it was announced that the hospital had received possession of an additional grant of six acres of ground and a portion of the buildings of the former asylum from the city corporation of Belfast.

A hearty vote of thanks to Lady Pirrie for presiding was passed on the motion of Professor Lindsay, chairman of the board of management of the hospital.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Cases of Bubonic Plague in a Paris Hospital.

AT a recent meeting of the Société Médicale des Hôpitaux Mr. P. Teissier made mention of 43 cases of bubonic plague treated at the Hôpital Claude Bernard from August to December, 1920, during an outbreak of the disease in Paris. In all the cases the diagnosis was controlled bacteriologically; 9 proved to be severe forms of the disease, 17 were of moderate severity, 17 were mild forms. All the patients were cured. Mr. Teissier has come to the conclusion that serum should be injected without delay as soon as the disease is suspected, and that the treatment should be intensive. These two principles were adopted in the treatment of his own patients, who were given injections of serum from the Pasteur Institute. Mr. Teissier recommends a daily intravenous injection of 100 c.cm. of serum, and if the first injection has not caused the temperature to drop, two injections of 100 c.cm. on the next day. Some of his patients suffering from severe forms were injected with 800 c.cm. of serum in the course of eight days; in children between 6 and 10 the dose of serum was 40 to 50 c.cm. When dealing with the bacteriological findings Mr. Teissier said he thought that laboratory investigations should not merely consist in looking for Yersin's bacillus in the serous fluid or pus from the enlarged glands, and emphasised the necessity of a blood culture, since in most of the cases he has treated Yersin's bacillus has been present in the blood right from the onset of the disease.

Remuneration of Practitioners Treating Pensioners.

According to a French Parliamentary Act of March, 1919, the remuneration of practitioners who are treating ex-service men in receipt of disability pensions is a State obligation when they are consulted for sequelæ due to war wounds or diseases contracted in or aggravated by service. At the time the Bill was passed it was decided that the rate of remuneration was to be settled by arbitration. A committee was appointed to deal with this matter; since its formation meetings have been held, to which the various medical associations and syndicates have sent delegates. Decisions arrived at had to be sanctioned by the Ministry of Pensions and the Treasury: a decree has just been published in the Journal Officiel, standardising professional fees. In boroughs where there are less than 200,000 inhabitants 4 to 5 francs will be the fees for every attendance; in boroughs where there are more than

200,000 inhabitants the fees will be 8 to 10 francs. Each time a medical consultation is needed the rate of remuneration will be increased by 50 per cent.; travelling expenses must on no account exceed 1 fr. 50 per km.; surgical operations will be performed free of charge in State hospitals. The committee of the Union des Syndicats Médicaux de France held a special meeting to consider the decisions of the Minister of Pensions and protested against them, at the same time urging doctors to refuse to comply with the decree in the presence of the disabled ex-service men whom they attend. This attitude is due to the fact that the committee of the Union des Syndicats Médicaux de France is of opinion that the provisions made under the arrangements of the decree are not sufficient to secure adequate treatment for the men concerned.

Scottish Medical Students in Paris.

You have already announced the visit of Edinburgh medical students to Paris. Lectures and demonstrations on midwifery, to be delivered in English, have been organised in three of the hospitals for their benefit. This course was organised by Professor P. Bar in order to give Scottish students the opportunity of conducting a fair number of labours, since the course of practical midwifery is restricted in Edinburgh hospitals as compared with those of Paris owing to the relatively small number of confinements. On their arrival in Paris the Edinburgh students were greeted by some of the members of the Association Générale des Etudiants, who have arranged accommodation for them. Professor H. Roger, dean of the Faculté de Médecine de Paris, gave the students a warm welcome at the Clinique Tarnier. In the course of his speech he emphasised the common Celtic origin of the Scottish and French nations, and said that for that reason he wished to greet them as fellow countrymen rather than as foreigners; he also referred to the great popularity of the works of Sir Walter Scott in France, and finally commended the industry, culture, and hospitality of the Scottish people, expressing the hope that those whom he was addressing would find an equivalent hospitality here. It was arranged that the men students should attend the Baudelocque and Tarnier Cliniques; women students, of whom there are 17, will attend the clinic of the Hôpital de la Pitié. The professors who will superintend these special courses are MM. P. Bar, A. Brindeau, A. Couvelaire, J.-L. Faure, and P. Lequeux. In a few weeks' time new groups of Scottish students will replace those who are at present in Paris.

March 31st.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Malaria in Austria.

BEFORE the war malaria was a very rare disease in the part of the Empire which now constitutes the Austrian Republic. In Vienna, where all sorts of patients came together, cases from the southern districts were occasionally encountered, and students were always on the look out for one of these interesting and rare patients. But when soldiers were sent from the fighting lines in Italy, Serbia, Albania, Roumania, and Russia, malaria of all varieties prevailed, and it soon became necessary to organise a special malaria service. Apart from laboratories and other arrangements behind the fronts, a central malaria hospital was instituted in Vienna for treatment and study under a malaria board, to which all cases of the disease had to be reported. With the return of prisoners of war who had spent years of captivity in unhealthy districts (Siberia, Turkestan, Sardinia, Asia Minor), the numbers of new cases continued to increase. In Vienna alone there were no less than 10,610 cases of malaria caused directly by captivity; 1603 of these were first reported in 1920, the bulk being reported in 1919, when most of the homecoming prisoners arrived in the country. All these cases were carefully examined before permission was granted to mix with their people; cases requiring treatment were detained and properly dealt with. All infected persons are required to report as soon as symptoms return, and at least once a year, because exact records are kept of every case. Treatment is gratuitous and compulsory, and frequent public instruction is given as to the dangers of neglect of hygienic precautions.

Exploratory Laparotomy in a Hermaphrodite.

The problem of definitely settling the question of sex in a case of hermaphroditism is at times so difficult as to baffle all hitherto applied methods. It is well known that individuals regarded as masculine and educated on these lines have proved after all to be really females, and vice versa. Professor Meixner recently resorted to laparotomy to discover the sex of a 9-year-old child. The child, who was shown at a recent meeting of the Vienna Medical Society, had two well-developed labia majora and a very large penis-like clitoris, but no vagina; rectal examination did not give a clear result as to presence or absence of internal female organs. On opening the abdomen a small uterus was found, with two appendages, which were recognised by all those present as a normal ovary; on the left side a small, brownish body was also present, which microscopic examination proved to be a rudimentary testicle. The child was manifestly a true hermaphrodite, but to all intents a female, especially as the testis was removed. An animated discussion followed the demonstration, in which the advisability of laparotomy was questioned. But Professor Meixner pointedly remarked that nowadays an exploratory laparotomy, even in a child, is much less serious than some other operations performed for less urgent indications on children and adults. The importance of determining the actual position in life of an individual in infancy was of such an overwhelming nature that the slight risk involved was admissible. This was also the opinion of the majority of those present.

Increase of Fees for Foreign Students.

By an Order of the Board of Education the fees payable by students at the institutes and laboratories of the medical faculties of the three Austrian universities have been raised in such a way that foreigners have to pay more heavily than Austrians. In the coming summer term the general increase of fees will be 50 per cent., but for foreigners it will be 2500 per cent.; and for the latter the fee for graduation will be 1000 per cent. of the present fee. The rate of exchange, now so favourable to foreigners, will thus be partly compensated, but the foreign student will still be able to study here with a very small expenditure of money. He will have to pay for the whole term as many times 250 kronen (equal to 2*s.*) as his hours of study during the week. A class on gynæcology (four hours per week) will cost him 8*s.* for the whole term, on materia medica (six hours per week) 12*s.* Special courses do not come under the scope of this Order. The increase of regular fees was necessary owing to the grant by the Rockefeller Foundation of $60,000 to the University for the purpose of laboratory and institute outfit, made on the condition that the numerous foreign students taking their classes here should be forced to contribute by increase of fees to the State expenditure for the universities. It was considered unjust that an impoverished State should enable foreign students to obtain first-class medical instruction not only very cheaply, but at a cost so far below that of equivalent education in their own countries. It is expected that by these means a sum of 5 millions of kronen will be raised for the above-mentioned purposes within one year.

The Effects of the War on the Number of New Practitioners.

The Vienna Board of Health has published, amongst other interesting figures, a few statistical data as to the number of medical men who began practice in this city since the beginning of the war. Of the following figures the first after the date is the number registered, the second the number who still remain in practice in Vienna—1914 (from August 1st), 107-15; 1915, 104-28; 1916, 49-18; 1917, 60-25; 1918, 256-161; 1919, 424-332; 1920 (till end of September), 302-248. At the beginning of the war many doctors came to Vienna as refugees from country occupied and devastated by the Russians; and after the break up of the empire in 1918 all, or nearly all, practitioners of German origin in the various districts of the empire were driven away by the new governments and thereupon settled down in Vienna. They soon found out that the city could not provide a decent living for all of them, and some went into country places or changed their occupations altogether and became tradesmen or clerks.

The First Female Director of a Dental Clinic, and Unique Dental Conditions.

Dr. Erna Greiner is the first female dental surgeon appointed as director of a dental clinic in this country. The appointment is at the dental clinic in the Rainer Spital, our chief hospital for war invalids. The new chief is highly esteemed by patients and colleagues. In this hospital the dental cases met with are of an unusual type and severity, being mostly direct war injuries in the shape of partial or total loss of teeth. These are chiefly visible in the prisoners of war who returned recently from Siberia. The pathological changes of the dentures are more severe than any before seen in this country. The majority of these patients had suffered from scurvy, so that their teeth had become loosened and displaced, and when the men came under better hygienic conditions their teeth became firmly fixed in the new positions. In some cases renewed attacks, perhaps in the following year, loosened them once more, and the abnormality of position was sometimes fantastic. The masses of tartar deposit found on the teeth of some prisoners of war were huge—layers of more than a centimetre in thickness were found. Such cases were shown to the Viennese learned societies, as their conditions were unique, at least for this country. Elaborate treatments were devised to rotate displaced teeth into normal positions, or at least into positions where they might be used, but in many instances artificial teeth were found to be preferable.

Health of Vienna.

An unusually prolonged period of glorious sunshine and dryness has been enjoyed for more than four weeks in this city, the average being eight hours of sunshine daily and less than three millimetres of rain for the month. The health of the population has naturally benefited. Diseases of the respiratory tract have been rather frequent, owing to the dust and wind, whilst diseases of the alimentary canal, as so often happens in periods of bright weather, became infrequent. A constant increase of diseases of the circulatory system has been manifest for several years, perhaps due to the mental strain and over-exertion of the last few years. A mild epidemic of influenza which is prevalent at present is, no doubt, also alleviated by the bright weather, as formerly March used to be the month for colds in the head in this city. These colds are now slight and of short duration. The mortality has also been lower than in any of the previous 18 months.

April 1st.

AUSTRALIA.

(FROM OUR OWN CORRESPONDENT.)

Federal Health Department.

THE Prime Minister has announced that a new Department of Public Health will be created with a special Minister in charge. Hitherto the Quarantine Act has been administered by the Customs Department, with a medical Director-General. Mr. Hughes stated that the representatives of the Rockefeller Institute now in Australia, Dr. Heiser and Dr. Sawyer, had undertaken that their institute would supply several experts if the Commonwealth Government would inaugurate a special department of public health. After conference with Dr. J. L. Cumpston (the Director), it was decided to inaugurate a new department by the establishment of research laboratories in various parts of Australasia. A list was given which comprised Bendigo (Victoria) Port Pirie (S. Australia), Lismore (N.S.W.), Rockhampton, Mackay, and Cairns (Queensland), Darwin (N. Territory), Port Moresby, Thursday Island, and Rabaul. The terms of the arrangement with the Rockefeller Institute were not disclosed, and it is probable that the conjunction has political rather than scientific foundation, since there is likely to be opposition to any new Federal expenditure.

Mysterious Death of a Sydney Doctor.

The remarkable circumstances which led to the death of Dr. C. Tozer, of Sydney, have not been further investigated owing to the continued illness of Mrs. Mort, who is detained on suspicion as the result of an inquest. The late Dr. Tozer was a graduate of Sydney University and a well-known figure in New South Wales, although little more than 30 years of age. He had played cricket in inter-State matches and was a batsman of the highest class. He had also a good war record. So far as meagre details are disclosed, it appears that he and Mrs. Mort had known each other for many years. The lady is supposed to have been addicted to drugs and was under medical care. Her husband asked Dr. Tozer to call and see her professionally. He went to visit her and after some hours was found dead in the room with a bullet wound in the head. Mrs. Mort was in another room in a state of collapse, from which she has not yet recovered sufficiently to allow of her attendance at any judicial proceedings. The latest report was that her condition showed no improvement. She was committed for trial after the coroner's inquiry.

Research on Native Fauna.

The Victorian Government has granted some 80 acres of mountain land in the district round Healesville to Dr. Colin Mackenzie as a farm on which Australian native animals may be kept in their original condition and observed as to habits and food proclivities. Dr. Mackenzie will make this an important adjunct of the Research Institute which he has successfully founded in Melbourne for the study of the comparative anatomy and developmental changes in native animals. His work on the comparative anatomy of the cæcum and vermiform appendix in Australian mammals, and his research on the glandular system in the platypus are already well known to your readers.[1] The importance of having work of this character done is emphasised by the fact that some of the native animals are already almost extinct.

Friendly Societies.

The dispute between the Victorian Branch of the British Medical Association and the lodges has almost reached a final stage in that all the objectors have accepted the terms demanded by the branch except the Manchester Unity Independent Order of Oddfellows. How long peace is likely to continue is problematical, as in consequence of the constant increase in prices and wages the medical men will possibly soon be compelled to insist upon a further increase in the lodge remuneration. The advance which caused the prolonged dispute only amounted to about *4d.* a week. Casual labour at present demands and obtains from 15*s.* to 25*s.* a day, while domestic servants' wages range from 25*s.* to 60*s.* per week and food. No advance has been made in the general standard of medical fees.

Feb. 8th.

---

[1] THE LANCET, 1916, i., 183.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—A meeting of this society will be held in the Gymnasium (old Board Room) of the Miller General Hospital, Greenwich, to-day, Friday, April 8th, at 8.45 P.M. Dr. A. M. Cato, the President, will occupy the chair, and Mr. C. J. S. Thompson, curator of the Wellcome Historical Medical Museum, will give an Historical Sketch of Military Surgery from the Earliest Times, illustrated by lantern slides.

A MODEL HYGIENIC CENSUS:

HOSPITAL AND HEALTH SURVEY IN CLEVELAND, OHIO.

THE Hospital and Health Survey of Cleveland, Ohio, has been made at the request of the Cleveland Hospital Council, a body representing 20 hospitals with a total of 3088 beds, by a committee appointed in October, 1919. The work was initiated with a view to promoting the public health and diminishing the number of preventable deaths in a particular American city, but the result has been a series of reports of more than local interest. Eleven paper-bound volumes containing in all 1000 pages may appear to be more than the subject should demand, but the task before the committee has involved the consideration of past history and present conditions and the visualising and providing for probable future development.

Founded in 1796, incorporated as a village in 1815, and chartered as a city in 1836, Cleveland is now the largest city in the State of Ohio, and the fifth city in size in the United States, having a population of about 800,000. It occupies an area of 58·7 square miles and extends for about 20 miles along the southern shore of lake Erie, being situated on both sides of the Cuyahoga River, where it flows into the lake. It stands 600 feet above sea-level, upon a soil which associates gravel and sand at some points with shale and clay at others. As may readily be appreciated, the lake and river, which combined to invite the founding of a town and to facilitate its early sanitation, are not unconnected with the problems that accompany a population already approaching a million. Sewers which empty themselves into a lake, adapted also for the dumping of drier refuse, have to be taken into serious consideration by those concerned with the purity of a city's water-supply, and the health of a population which in hot weather seeks its bathing beaches.

We are little concerned here with the bathing beaches that invite a population liable to experience 92° F. in May, 100° in August, and 98° in September, but it is necessary to remember such figures in reading the Survey not only where it deals with water. They are fully as relevant to the consideration of housing and house sanitation, the collection of refuse, and questions of health generally. Lack of housing accommodation and over-production of refuse in crowded areas are among our own problems, and we, too, in some of our cities find conditions aggravated by the presence of foreign elements of population not over-zealous for cleanliness. In any case, the Survey of Cleveland's difficulties contains lessons applicable, *mutatis mutandis*, to questions of public health that are cosmopolitan.

In the first volume of the Survey general introductory matter is followed by the consideration of water-supply, sewage disposal, and housing, including the sanitation and environment of dwellings, some of which are described in detail. The difficulty of rendering and keeping slum dwellings sanitary is not confined to Cleveland, and some of the photographs which illustrate its waste places might have been taken in many cities of the old world as well as in the new. Photographs, by the way, can afford but little more than arid impressions of dismal streets and untidy back yards. They are as inadequate for the representation of the horrors of decaying refuse and filth as they are for recording the turbulence or the majesty of a stormy sea.

The second volume, devoted to Public Health Services and Private Health Agencies, contains details of organisation of an interesting character and some outspoken criticisms. The coroner system, for example, which exists in the United States for much the same objects as with us, is not only condemned as a whole as presenting opportunity for "graft" and for the covering up of crime and preventable deaths, but on the same page it is frankly declared that as long as coroners and their medical examiners and assistants are selected with a view to their political usefulness rather than for their fitness for their posts "our cities, and among them Cleveland, will continue to be ill-served in this respect." We are inclined to envy the authors of the Survey their apparent freedom from anxiety on the score of possible libel actions (taking into consideration the fact that there cannot be many coroners in Cleveland) as well as to sympathise with them in their desire to see the coroner's office rendered useful and effective. The struggle of THE LANCET in a like direction in the past will be remembered by all familiar with its history. We also note here that Boston and New York have solved the difficulty by substituting a "medical examiner" for the coroner. In a country where so much independence is allowed to local legislatures we may learn some day that Cleveland or Ohio has done the same. There is, however, one subject in Cleveland which the Survey confesses "must be approached in a tactful manner because of the large amount of capital involved," patent medicines to wit. It is also recognised that many people buy them and practise self-medication, and that local newspapers exist largely upon their advertisements. We sympathise here with the authors of the Survey. We are not ourselves afraid of criticising the quack nostrum vendor or the newspapers who advertise his wares, but we recognise the weight of his financial interests and his vested rights. We observe, without much hope of its efficacy, that as a partial remedy at Cleveland a committee is suggested to examine and obtain the cessation of the worst advertisements and to find for the newspapers affected others of an innocuous character.

Part VIII. of the Survey is devoted to Education and Practice in Medicine, Dentistry, and Pharmacy, and Part X. to Hospitals and Dispensaries. Hospital service and its maintenance must everywhere depend largely upon traditional usage peculiar to the country concerned. The maintenance of hospitals has for its object the provision of institutional medical aid for those who cannot pay for it at the expense of others who can, and therefore much must depend upon the willingness or power of the wealthy to tax themselves, and upon the willingness or power of the legislature to institute taxation. These are local conditions affecting different countries in different ways. In such a work as the Survey, however, interesting records may be found of experience obtained in such matters as the contribution of patients to hospital funds and the value of "social service" in supervising and ameliorating conditions in the homes of poor patients. It is pronounced impossible in Cleveland in present circumstances to discharge all patients to convalescent homes, and at the same time it is recorded that visits to 200 discharged patients found 87 per cent. of them in home environment unfavourable to convalescence. The problem of convalescent care is dealt with briefly, but valuable suggestions are made in a memorandum by Dr. Frederic Brush, of New York.

CHILD HEALTH WORK.

The report drawn up by Dr. Josephine Baker gives a clear and comprehensive account of the various functional activities coming under this heading. They include prenatal, maternity and infant care, and the care of children under school age; also schools, institutions, and dispensaries for children. Under each of these subdivisions both the present status and needs, as well as recommendations for the future, are set forth in some detail, in accordance with the two fundamental bases laid down for effective child-hygiene work, these being (1) that prevention of disease is the first consideration, with such corrective health measures as may be necessary to ensure a normal physique during childhood and sound health during adult life; and (2) the necessity for continuous coördination and effective health supervision from the prenatal period through adolescence.

The three main criticisms of the organisation as it stands at present are the lack of coördination of the activities for child welfare as a whole; the weakness—apart from antenatal work—on the side of prophylactic measures; and the tendency, repeatedly referred to in the course of the report, to view the immediate results of any given effort for child hygiene as an adequate test of its success, whereas it is, of course, only after the lapse of time that the measure of success achieved can be truly gauged—e.g., proper maternity service should be measured not only by the reduction in the maternal mortality-rate but by the future health of the mother and child.

Various ways are suggested for meeting the existing lack of coördination, one of them being the establishment of a Central Child Hygiene Council, which should, among other duties, coördinate the work of all public and private agencies, and also maintain a central clearing house to receive and tabulate all essential statistics on child-welfare work, and to act as a link between the executive groups. The second criticism, dealing with the inadequate attention paid to the prophylactic side of the work, is met by various specific and very practical recommendations under each heading.

Some of the more important sections of the report deal with the antenatal and maternity work done in Cleveland. The marked reduction in the university district of the stillbirth-rate among cases receiving prenatal care—these forming a very limited proportion of the total number—is quoted as showing that Cleveland needs three times the facilities it possesses at present for prenatal care. Dr. Baker adds:—

> The figures given by the Maternity Centre Association of New York City show that among 502 women supervised during their pregnant periods and receiving proper care at time of confinement there was only one death. Maternal mortality ranks second highest in the list of causes of death among women between 15 and 45 years of age in the United States, being exceeded only by tuberculosis. Reduction in the death-rate of mothers and babies as a result of prenatal care can be effected with mathematical certainty. It is simply the question of providing the type of case that has already been recognised and standardised.

Among the various recommendations appended to this section are included suggestions as to the composition and function of a committee on Prenatal Care as a part of the Central Child Hygiene Council; while under the section of Maternity Care important and far-reaching recommendations are made, dealing with birth registration (at present not more than 80 per cent. of the births occurring in Cleveland are reported to, and registered by, the Bureau of Vital Statistics of the Division of Health), with hospital facilities, and with a suggested programme for the control of midwifery.

In the section on School Health Supervision many important points are brought out, such as the disproportionate time given to finding defects and recommending treatment compared with that given to seeing that those defects are remedied and the child's mode of living and home surroundings improved. In the Department of Medical Inspection for the school year 1917–18 32,918 children were found to have physical defects, while only 38·1 per cent. of these were reported as having been corrected, these corrections being, moreover, almost all of the most obvious defects, while defects such as anæmia, scoliosis, and defective nutrition were uncorrected.

VENEREAL DISEASE.

In the past, apart from such treatment facilities as have been available through the dispensaries, the city hospital, and the general medical profession, no special steps have been taken, or work performed, for combating venereal disease. A special programme has now been drawn up containing a large number of recommendations for the diminution of the incidence of such diseases. Amongst these recommendations are the following, which for the sake of convenience may be placed under three headings: (1) measures directed to the protection of individuals from exposure; (2) the elimination of environmental conditions favouring dissemination of venereal diseases: (3) provision and maintenance of facilities for diagnosis, treatment, and control of infected persons.

Under (1) come such measures as educational work in schools, homes, and churches for the purpose of character building, the instruction of the public on hygiene, the dissemination of knowledge on the prevalence, method of spread, and serious consequences of V.D., the improvement and regulation of amusements, recreations, and athletic organisations, the safeguarding and bettering of home surroundings, and the encouragement of early marriage.

Under (2) are grouped such measures as the elimination of the commercialised aspects of prostitution, the prevention of solicitation, and the prosecution of persons employing premises for illicit purposes.

Under (3) are included such measures as the maintenance of advisory clinics fitted with facilities for early diagnosis and efficient treatment. The control of infected persons is provided for through instruction on the subject of venereal diseases by the physician responsible for treatment. Definite standards of cure are to be established, and penalties enforced for exposing others to infection. In order to stimulate and direct the campaign against venereal diseases the report recommends the establishment of a special bureau in charge of a full-time medical man. This medical officer in charge of the bureau is a full-time official, having under his command various assistants (such as nurses, clerks, &c.), in order that he may be able to conduct a comprehensive campaign for the eradication of gonorrhœa and syphilis. The duties of such a bureau will be the organisation, the supervision, and the stimulation of treatment facilities, the returning to treatment of those patients who fail to continue under medical care until cured, and the education of the public upon the methods of contraction, spread, control, prevention, and treatment of venereal diseases. The duties of the chief of this bureau in completing a comprehensive programme would preclude any clinical work, either private or public. In order to gain the absolute confidence of the medical profession he should have had clinical experience in the treatment of V.D., although he should not be required or permitted to undertake clinical duties.

The following plan of organisation for the venereal disease bureau of the Division of Health is suggested:—

Working under the M.O. in charge of the bureau is a staff consisting of two nurses, an agent, and clerks. The main function of the bureau is apparently educational—the instruction of the public upon the general subject of prevalence, mode of transmission, serious consequences of syphilis and gonorrhœa, and the necessity for prompt and continuous treatment. This educational work is to be undertaken by means of lectures, cinemas, and pamphlets, and is directed so as to reach all classes and ages of the community. A special "follow-up" system is recommended for such patients as fail to complete their course of treatment at the venereal clinics by means of cards being sent out in sealed envelopes.

Finally, certain recommendations are made with regard to alterations in legislation. The campaign that is contemplated is, however, mainly of an educational nature, and does not include an appreciable alteration or extension of the legislation dealing with these diseases. The "age of consent law" should, according to the memorandum, be amended so as to protect young boys as well as girls under 16, and more protection is to be given to mental defectives generally. Provision is made for the work of women police, and an educational campaign is to be undertaken amongst female prisoners appearing at police-courts. Altogether the crusade sketched in the memorandum is very complete. It should certainly result in a marked diminution of venereal disease in the town of Cleveland.

MENTAL DISEASE AND MENTAL DEFICIENCY.

The Cleveland Hospital Council directed that all hospitals and kindred organisations in the city of Cleveland should be passed under review, and a section of the report deals with the medical and social problems arising from mental disease and deficiency. It is prepared by Dr. Thomas W. Salmon and Dr. Jesse M. W. Scott, and contains 511 pages of interesting details describing the provision made for the insane, for mental deficiency, for epilepsy, and the methods of dealing with delinquents, the juvenile courts, and the agencies for correction, welfare work, after-care, and the treatment of atypical children. A Survey such as this is extremely valuable in enabling the community to take stock of its medical and social work; it gives the public an opportunity of knowing what is done and learning some of the defects, and at the same time it indicates in what direction new legislation is needed.

If any doubt existed in the minds of the Cleveland City Fathers that the mental annexe of the Cleveland City Hospital needs to be reconstructed, the frank statements in this report will convince the most reactionary. We are told:—

> "The wooden floors are nearly worn through, and it is impossible to keep them clean. ...... A short time ago a woman pulled up part of the floor in one of the rooms and escaped through the hole she had made. Rats and bed-bugs are numerous. ...... There is no classification of patients, the anxious and depressed occupy the same ward. Childhood and old age mingle. ...... The hard-working, self-respecting American woman, who has reared her children in a clean American home, ... listens all day to the curses of a young prostitute in a bed adjoining hers."

Plain speaking such as this must lead to reform, especially when accompanied by a striking series of photographs contrasting what is with what should be.

It is rather singular that in stating the defects of the existing system of treatment the same complaints are made with which we in this country are familiar—viz., that there is lack of provision for the early treatment of mental disorders. Physicians complain that there is no method of securing temporary observation of doubtful cases, especially for the poor, and that the present procedure prevents patients from applying for treatment in the early stages of their illness. One would have thought the City Hospital referred to was exactly what is needed, but this appears to be so managed that—

> "When one leaves the general wards of the hospital and crosses a little strip of grass to the doors of the building devoted to mental cases he leaves behind him not only the medical science of the present century, but in large part its humanitarian attitude towards disease and suffering."

It is surprising to find that there are no laws in Ohio providing for the inspection of private institutions for the insane, and anyone can at any time, regardless of qualifications, set up a private sanatorium for mental cases. The State mental hospitals are managed by a State Board of Administration, and there are no local boards of managers. The four salaried members of this board control 21 institutions, including the eight State mental hospitals. This centralisation of responsibility does not seem satisfactory. The Cleveland State Hospital is overcrowded, 1737 patients in space designed for 1450. In 1919 617 new patients were admitted, and about 10 per cent. of the patients die annually. It is parsimoniously administered throughout. The medical superintendent receives only $2500 yearly. The reference to this hospital concludes:—

> "The superintendent is trying in the face of these conditions to make his institution a hospital in fact as well as in name. ...... He will inevitably fail, if the people of Cleveland are unable to induce the legislature to change the policy of neglect that keeps its work upon the asylum level."

It is well to note the breadth of view which pervades the report. Custodial care in an asylum is repeatedly contrasted with treatment in a hospital, an attitude of mind needed in our own country. Space will not permit any reference to the great institution in Ohio containing 3125 feeble-minded persons, or of the excellent organisation dealing with delinquency criminals and other social failures.

It is disappointing to find that a wealthy State such as Ohio is not more advanced in its care of the insane, and at first reading it may be concluded that we have little to learn from the report. But before we can judge we ought to have one equally frank report of the conditions obtaining in one of our larger English counties. It is doubtful whether such a report would give ground for self-complacency. Although we may perhaps safely conclude that English mental hospitals and English lunacy administration are better than appears to be the case in Cleveland, we must admit that not all our public institutions really deserve the name hospital, whilst everywhere there is still a grave lack of any provision for the effective treatment of a poor person in danger of mental breakdown. The reproach remains that voluntary patients cannot be received in any of our public mental hospitals. If anyone in fear of such illness should apply for admission the only possible answer is in effect—

> "Go away; and when you get worse perhaps a doctor will sign you up. Then you must see a magistrate and persuade him to sign a Reception Order. If you will bring this with you we will gladly do all we can!"

HEALTH AND INDUSTRY.

The section devoted to a Survey of Industrial Medical Service and the Employment of Women and Children is not the least interesting of this series of reports. Dr. Wade Wright deals with medical service after carefully studying over 100 industrial concerns.

He found that 43 per cent. of the employees work in establishments employing 1000 or more, only 2·6 per cent. of all organisations; hence, by concentrating at first on the few larger concerns health supervision could be ensured for a large proportion of the workers. He reports that industrial medical service as at present conceived is comparatively new, crudely developed, and far from being standardised; while industrial nursing is perhaps even less standardised. Here objection is rightly raised to nurses freely administering sedatives for headaches and the like, and cocaine for removal of foreign bodies from the eye. Nevertheless, he remarks as worthy and creditable that about one-half of the industrial workers of Cleveland are upon occasion receiving some sort of medical attention in industrial plants, the cost at one large establishment amounting to $10.92 a year per employee and at another to $11.23. Industrial concerns, especially the smaller ones, are urged to combine for the purpose of starting industrial dispensaries in order to secure a medical and nursing personnel. Full medical care of the workers could by this means be ensured and possibly also of their families. Insistence is laid on the value of standardised medical records and on not accumulating useless statistical material; otherwise accurate estimates and comparisons of losses due to accidents and illness cannot be made or steps for their avoidance planned. A frequency rate of 93·7 accidents per 1000 workers per year, with an accident severity rate of 4·5 days lost per worker per year, which occurred in Ohio in 1914, gains insignificance when compared with a frequency rate of 201·7 accidents, with an accident severity rate of 2·6 days lost in 1919. Sickness, which leads to an average of seven days of lost time a year per worker is even more important, though studiously neglected; yet industry presents an unparalleled opportunity for detecting the causation of disease and observing treatment, since here many persons are brought together into groups, each of which is exposed to a different industrial environment.

The need for physical examinations is stressed, not for the purpose of rejecting workers but for selective placement. Cripples and persons handicapped by orthopædic conditions, deaf and dumb, partially and totally blind, and even pronounced and recognised mental defectives were found usefully employed. But, to prevent industrial unrest, psychological selection is required to avoid the burdens of fatigue and of unhealthy working conditions falling on those of deficient mentality. Dental service is strongly advocated; wherever it has been installed it has been enthusiastically accepted. The rôle an industrial medical service can play in combating tuberculosis and venereal diseases is noted. The need for special orthopædic work for rehabilitating industrial cripples is reviewed. Industrial hospitals are called for to treat the workers and to train industrial physicians and nurses. Finally, the establishment of a Bureau of Industrial Hygiene within the Municipal Division of Health is strongly recommended.

There can be little doubt that if action follows on the lines suggested by Dr. Wade, Cleveland will see a new industrial revolution.

The subject of Women and Industry is shortly reviewed by Marie Wright, who points out the great need for the working environment of women to be healthful since domestic duties render them less likely than men to take healthy recreation.

Recently more has probably been done for women than for men in order, during scarcity of labour, to attract them into employment; rest rooms, change rooms, lockers and overalls have appeared, and with them an increased feeling of well-being and self-respect among the workers. Cafeteria (canteens) have often been provided and welfare directors appointed for women and girls only. Still the need for extension of these things and for improved toilet facilities and washing accommodation is pointed out, and also the importance of providing, wherever possible, seats at work for intermittent or occasional use. In one particular Cleveland is behindhand—viz., in permitting the employment at night of women over 21 years of age; this practice is rightly condemned. Generally speaking, the recommendations made are sound, and fall into line with those put forward by Dr. Wright.

The Industrial Employment of Children is reported upon by Florence V. Ball:—

The Child Labor Law of Ohio, which is often cited for its excellence, prohibits the employment of boys under 15 and girls under 16 years of age. But "if the law is not enforced its excellence is without virtue," and reports were received from all sides of under-age children being regularly but illegally at work. Possibly the conditions may be better now that labour is less scarce. Nevertheless, improved methods and an increased personnel are called for to enforce compliance with the law upon both employers and parents, to whom children too often represent so much potential earning power for the family income; indeed, many children were employed doing adults work because of the labour shortage. Care and supervision of juvenile employment, in regard to alternate sitting and standing at work, change of posture, the wearing of sensible working clothes, a nourishing diet, plenty of sleep and fresh air, are pointed out to be much more important than for adults if the workmen of the future are not to be irretrievably damaged during adolescence.

Attention is particularly directed to juvenile employment in the manufacture of hosiery, the metal trades, printing factories, and telephone and telegraph work. Blind-alley occupations for boys are commented on, and the necessity is stressed for apprenticing each youth to a definite trade; left to themselves they will work themselves out at piece work in order to earn comparatively high wages without regard to their future or their health; in this connexion street-trading is specially condemned.

Medical examination of employed juveniles is claimed to be an inevitable extension of the medical inspection of school children, which has recently been started in Cleveland and is already of proved value. A medical permit preliminary to industrial work is suggested to be medically endorsed periodically as noted on the permit, and upon every change of employment. The author points to the need for scientific investigation into the effect of different classes of work upon the physique, morbidity, mortality, fatigue, and physiological development of adolescents; and recommends it should be undertaken.

This portion of the report has been most carefully considered and thought out; standards of physical fitness are suggested and methods of examinations set out; the organisation of a Junior Vocational Bureau is planned; and finally the recommendations requiring legislation are clearly summarised.

NURSING.

The Nursing Survey, which was in charge of Miss Josephine Goldmark, Secretary of the Committee for the Study of Nursing Education, is not only of inestimable value as an exhaustive study of the existent nursing services, but by the recommendations made it has revealed the tremendous possibilities which may be achieved by each department of nursing in health administration throughout the State. To study the "Nursing" Section of this Survey is to realise more forcibly than hitherto the vital part which must be played by the trained nurse as a "missioner of health" in getting over to the individual members of the community the laws of health which can alone evolve a healthy nation.

In reviewing the *Hospital Training Schools* in Cleveland it is obvious that nursing authorities are facing the same difficulties in producing an efficient nursing service as our authorities are facing in this country, the most prominent of which are financial difficulties: dearth of candidates; inadequacy of medical service for training; difficulty of arranging affiliated training that nurse students may have a broad general training; failure to correlate the theory and practice of nursing owing to lack of sufficient direct supervision by the instructor and to lack of suitable equipment.

The recommendations suggested to ameliorate some of these difficulties include—

(*a*) The establishment of a university training school which would bring about the independence of the hospital and training school, and would ensure better students and better instruction. The university would give a definite period of college training, an equal length of time for hospital training, and a final academic period for additional courses in nursing specialties. Such a scheme has been worked out in other States in America with great success.

(*b*) An adequate system of cost accounting in the training schools, which would include a separate budget for the training schools and would state the financial value of work done by the student nurses and the saving to hospitals from the utilisation of their services.

(*c*) Compulsory minimum educational requirements. (An urgent need in this country as a means of reaching the right type of woman and increasing the number of candidates.)

(*d*) Improved equipment and qualified instructors for the education of the nurses.

(*e*) Affiliation of the different hospitals in order to furnish adequate clinical facilities for the general training, and special courses arranged for students intending to enter the field of public health.

(*f*) The payment of all lecturers.

(*g*) The provision of ward helpers, which would enable the three years' hospital course to be reduced. The principles underlying such reduction to be (1) that all nurses in training should have the same basic education, after which they may be graduated with the certificate or diploma of nurse; (2) that, in addition, courses should be provided leading to a special diploma for public health nurses, for teaching and administrative positions in hospitals, and for specialties in private duty.

The Western Reserve University has provided an excellent course in Public Health Nursing for district nurses; such a scheme is highly commendable, and could be developed with advantage in this country.

The most commendable feature of the *Public Health Work* in Cleveland is the correlation of the various services under the Central Nursing Committee, which represents the Division of Health of the City Department of Welfare; the Board of Education; Babies Dispensary and Hospital; District (Visiting) Nurses Association; Anti-Tuberculosis League; Western Reserve University Teaching District.

The existence of such a committee has proved a valuable asset for public health nursing in Cleveland, and results in a generalised system maintaining a uniform high standard of nursing care, and lessens the chance of duplication and misunderstanding among the various agencies at work.

CONCLUSION.

This Survey of the Public Health Services of Cleveland, which is a realisation of its responsibilities in health education by the Western Reserve University, is impressive; splendid work is being done in a district having an estimated population of 65,000 inhabitants. One of the poorest and most congested areas has been set aside as a practice field for the practical training of public health nurse students, and has proved a valuable laboratory for experimentation in policies and methods of an educational character. Industrial nursing is being widely developed, and, although one of the youngest of the Public Health Services, it is nevertheless one of the most important.

In dealing with *Private Duty Nursing*, the employment of trained attendants has been a subject of lively controversy, but it is rightly felt that the framing and enactment of suitable legislation must first take place before trained attendants are officially recognised.

One gathers from this Survey that the medical, educational, and health authorities of Cleveland are obviously alive to the fact that, unless women responsible for carrying out prescribed medical treatments and instructing the people in the laws of healthy living are expert and fully qualified to do so, the efforts of the medical profession and health authorities are proportionately frustrated. It cannot be denied that the work of the medical profession could be immensely enhanced by a body of educated women possessing not only a sound academic education, but a professional education qualifying them for the important work of bringing to the people the benefits of medical and sanitary science. Surely the moment is ripe for such a body as the Ministry of Health to make a survey of the nursing services available in this country, that we may realise where the weaknesses lie, and by adjustment and development of all available clinical opportunities may more adequately meet the needs of the community.

The concluding volume, Part XI., contains information on the method of survey adopted, under the title Method of Making a Community Diagnosis, followed by a Bibliography of Survey, in itself a valuable work of reference. and an index.

URBAN VITAL STATISTICS.

(Week ended April 2nd, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18½ million persons, the annual rate of mortality, which had been 15·2, 13·9, and 13·0 in the three preceding weeks, was again 13·0 per 1000. In London, with a population of 4½ million persons, the death-rate was 13·2, or 1·6 per 1000 above that recorded in the previous week, while among the remaining towns the rates ranged from 6·2 in East Ham, 7·5 in Barrow-in-Furness and in Wimbledon, and 7·7 in Enfield, to 20·8 in Oldham and in Sunderland, 21·3 in Middlesbrough, and 23·3 in Barnsley. The principal epidemic diseases caused 237 deaths, which corresponded to an annual rate of 0·7 per 1000, and comprised 69 from infantile diarrhœa, 62 from diphtheria, 49 from whooping-cough, 37 from measles, 17 from scarlet fever, and 3 from enteric fever. Measles caused a death-rate of 4·1 in Stockton-on-Tees and whooping-cough of 1·3 in Sunderland

and 1·5 in Rotherham. The deaths from influenza, which had been 149, 151, and 121 in the three preceding weeks, rose to 130, and included 44 in London and 5 in Manchester. There were 3535 cases of scarlet fever and 2689 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 3609 and 2777 respectively at the end of the previous week. During the week ended March 26th 3 cases of encephalitis lethargica were notified in the County of London, and comprised 1 each in Camberwell, Hampstead, and Wandsworth. The causes of 35 of the 4643 deaths in the 96 towns were uncertified, of which 8 were registered in Birmingham and 3 each in London and South Shields.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2¼ million persons, the annual rate of mortality, which had been 18·5, 17·8, and 15·3 in the three preceding weeks, rose to 15·5 per 1000. The 353 deaths in Glasgow corresponded to an annual rate of 16·7 per 1000, and included 34 from whooping-cough, 7 from influenza, 5 from infantile diarrhœa, 3 from scarlet fever, 2 from diphtheria, and 1 from measles. The 132 deaths in Edinburgh were equal to a rate of 15·4 per 1000, and included 4 from diphtheria, 3 each from measles and influenza, and 1 from infantile diarrhœa.

Irish Towns.—The 156 deaths in Dublin corresponded to an annual death-rate of 19·2, or 2·4 per 1000 above that recorded in the previous week, and included 5 each from infantile diarrhœa and influenza. The 140 deaths in Belfast were equal to a rate of 17·4 per 1000, and included 8 from whooping-cough, and 1 each from diphtheria, infantile diarrhœa, and influenza.

VITAL STATISTICS OF LONDON DURING THE YEAR 1920.

IN the accompanying table statistics of sickness and mortality in the City of London and in each of the metropolitan boroughs are summarised for the 52 weeks of the year 1920. With regard to the notified cases of infectious disease, it appears that the number of persons reported to be suffering from one or other of the ten diseases specified in the table was equal to a rate of 8·9 per 1000 of the population, estimated at 4,531,971 persons in the middle of the year; in the three preceding years the rates were 4·2, 4·4, and 5·9 per 1000 respectively. Among the various boroughs the rates last year ranged from 5·3 in the City of London, 5·4 in Hampstead, 5·5 in the City of Westminster, 5·9 in Chelsea, 6·5 in St. Marylebone, and 6·7 in Kensington, to 10·1 in Finsbury, 10·6 in Bermondsey, 10·9 in Fulham, 13·9 in Stepney, 14·1 in Poplar, and 15·7 in Bethnal Green. Excluding 2 cases of which the diagnosis proved incorrect, 16 cases of small-pox were notified during the year against 11, 1, 0, 35, and 26 in the five preceding years; of these 11 belonged to Poplar and 2 to Stepney. The prevalence of scarlet fever showed a considerable increase last year; 22,713 cases were notified, against 6110, 6811, and 12,931 in the three preceding years. Among the metropolitan boroughs the greatest proportional prevalence of this disease was recorded in Bethnal Green, Stepney, Poplar, Bermondsey, and Deptford. The Metropolitan Asylums Hospitals contained 4729 scarlet fever patients at the end of the year, against 1246, 1087, and 2841 at the end of the three preceding years; 21,538 new cases were admitted during the year, against 6056, 6676, and 11,750 in the three preceding years. Diphtheria also showed a marked increase in prevalence; 13,784 cases were notified during the year, against 8174 and 9479 in the two preceding years. This disease was proportionally most prevalent in Fulham, Islington, Holborn, Shoreditch, Bethnal Green, and Poplar. The number of diphtheria patients remaining under treatment in the Metropolitan Asylums Hospitals at the end of the year was 2615, against 1089 and 1845 at the end of the two preceding years; the number of new cases admitted during the year was 13,203, against 8256 and 9053 in the two preceding years. The prevalence of enteric fever was somewhat greater than in the two preceding years, but was considerably below other recent years, 391 cases being notified, against 779, 647, 463, 452, 358, and 344 in the six preceding years. The greatest proportional prevalence of this disease was recorded in Kensington, Fulham, St. Marylebone, Hampstead, Holborn, and Greenwich. The number of enteric fever patients admitted into the Metropolitan Asylums Hospitals during the year was 196, against 470, 446, 324, 271, 242, and 215 in the six preceding years; 15 cases remained under treatment at the end of the year, against 68, 50, 37, 32, 23, and 25 at the end of the six preceding years. The greatest proportional prevalence of erysipelas occurred in Fulham, St. Marylebone, Finsbury, Bethnal Green, Stepney, Southwark, and Deptford. The cases of puerperal fever notified during the year numbered 452, against 199, 158, and 313 in the three preceding years; this disease was proportionally most prevalent in Hammer-

* Including membranous croup

smith, Fulham, Poplar, Bermondsey, Battersea, and Deptford. The 156 cases of cerebro-spinal meningitis included 15 in Islington, 15 in Wandsworth, 14 in Stepney, and 11 in Poplar; while of the 42 cases of poliomyelitis, 7 belonged to Islington, 6 to Hammersmith, and 5 to Lambeth.

The mortality figures in the table relate to deaths of civilians actually belonging to the various metropolitan boroughs, and are obtained by distributing the deaths in institutions among the boroughs in which the deceased persons had previously resided. During the 52 weeks ended Jan. 1st last, the deaths of 56,038 London residents were registered, equal to a death-rate of 12·4 per 1000; in the three preceding years the rates had been 14·7, 18·6, and 13·4 per 1000. The lowest death-rates last year were 9·0 in Hampstead, 10·0 in Wandsworth, 10·4 in Woolwich, 10·8 in Lewisham, 11·1 in Paddington, 11·2 in Hammersmith, and 11·3 in Fulham; the highest rates were 14·4 in Stepney and in Southwark, 14·5 in Finsbury, 14·6 in Poplar, 14·7 in Bethnal Green, 14·9 in *Holborn*, and 15·4 *in Shoreditch*. The deaths from all causes included 4176 which were referred to the principal infectious diseases; of these, 4 resulted from small-pox, 1007 from measles, 207 from scarlet fever, 1009 from diphtheria, 759 from whooping-cough, 49 from enteric fever, and 1141 from diarrhœa and enteritis among children under 2 years of age. The death-rates from these diseases in the aggregate ranged from 0·3 in Hampstead, 0·4 in the City of Westminster and in the City of London, 0·5 in Chelsea, and 0·6 in St. Marylebone, in Holborn, in Wandsworth, in Lewisham, and in Woolwich, to 1·3 in Hackney, in Poplar, and in Bermondsey, 1·6 in Shoreditch, and 1·9 in Bethnal Green. Of the 4 deaths from small-pox 3 belonged to Poplar. The 1007 fatal cases of measles were 411 fewer than the average number in the five preceding years; this disease was proportionally most fatal in Hackney, Shoreditch, Bethnal Green, Southwark, and Bermondsey. The 207 deaths from scarlet fever were 42 above the average number; the greatest proportional mortality from this disease was recorded in St. Marylebone, Stoke Newington, Bethnal Green, and Poplar. The 1009 fatal cases of diphtheria were 349 in excess of the average number; this disease showed the greatest proportional fatality in Islington, Stoke Newington, Hackney, Finsbury, Bethnal Green, and Poplar. The 759 deaths from whooping-cough were 120 below the average; the highest rates from this disease were recorded in St. Pancras, Hackney, Bethnal Green, Stepney, Poplar, and Bermondsey. The 49 fatal cases of enteric fever were 37 fewer than the average, and included 5 in Southwark, 5 in Camberwell, 4 in Fulham, 4 in Poplar, 3 in the City of Westminster, 3 in Stepney, and 3 in Wandsworth. The 1141 deaths from infantile diarrhœa and enteric were 480 below the average; the proportional mortality from this disease was greatest in Kensington, Shoreditch, Bethnal Green, Stepney, and Deptford. In conclusion, it may be stated that the aggregate mortality in London last year from these principal infectious diseases was 13·6 per cent. below the average of the five preceding years.

The Services.

A DENTAL SERVICE FOR THE ROYAL NAVY.

NEW regulations have been issued for admission to the Royal Naval Dental Service. Dental mischief has been the cause of much disability, pain, and discomfort in the Navy, and it is well that steps should have been taken to provide officers and men with adequate dental treatment. The qualifications for admission to the service are as follows: The candidate being British, sound in mind and body, and willing to engage for general service at home or abroad, must be a fully qualified dentist registered under the Dental Acts. He must produce a favourable report from the responsible authority of his medical school, and must pass certain tests of physical fitness imposed by a board of naval medical officers. He must then present himself for examination and will receive appointment in accordance with the place which he obtains in the test of successful candidates. Possession of certificates from an Officers Training Corps will be worth additional marks at the entrance examination. Special arrangements are to be made to admit candidates from dental schools in the Dominions and Colonies. Successful candidates will be required to attend certain courses of instruction laid down by the Admiralty, when they will receive commissions as surgeon-lieutenant. A sensible precaution against slackness or rust is the provision of a post-graduate course of three months' duration. The course is given to surgeon lieutenant-commanders of after two years' seniority; it is optional, and those who take it will be accommodated at the Royal Naval College, Greenwich. The relative rank, pay, and allowances of the dental officers will be as follows.

Relative Rank in the R.N. Dental Service.

—	Military branch.	Army rank.
Surgeon Commander (D)	Commander.	Lieutenant-Colonel, but junior to that rank.
Surgeon Lieutenant-Commander (D).	Lieutenant-Commander.	Major.
Surgeon Lieutenant (D).	Lieutenant.	Captain.

Full Pay.

—	Year of 365 days.			One day.		
	£	*s.*	*d.*	£	*s.*	*d.*
Surgeon-Lieutenant (D)—						
On entry	401	10	0	1	2	0
After three years	492	15	0	1	7	0
Surgeon Lieutenant-Commander (D)—						
On promotion	593	2	6	1	12	6
After 3 years' seniority	629	12	6	1	14	6
„ 6 „ „	656	2	6	1	16	6
„ 9 „ „	730	0	0	2	0	0
Surgeon Commander (D)—						
On promotion	775	12	6	2	2	6
After 3 years' seniority	839	10	0	2	6	0
„ 6 „ „	912	10	0	2	10	0

Note.—20 per cent. of the rates of full pay, half pay, and retired pay are considered as due to the present high cost of living, and are subject to change on or after July 1st, 1924, and thereafter every three years, either upwards or downwards, according as the cost of living rises or falls.

Allowances.—Dental officers will be eligible for allowances on the same scale and under the same conditions as for medical officers of equivalent rank, except that "flag allowances" and "specialist allowances" will not apply.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Col. N. Tyacke is placed on retired pay, and is granted the rank of Colonel.

Lieut.-Col. T. E. Fielding relinquishes the acting rank of Colonel.

Lieut.-Col. A. R. O'Flaherty retires on retired pay.

Temp. Major E. H. Marshall relinquishes the acting rank of Lieutenant-Colonel.

F. J. Scrimgeour relinquishes the local rank of Major.

Temp. Capt. A. S. Plant to be Captain.

Temp. Capts. P. Kitchin and A. Cowes relinquish their commissions and retain the rank of Captain.

TERRITORIAL FORCE.

Capt. H. J. G. Wells, R.A.M.C., to be Adjutant of the R.A.M.C. School of Instruction, West Riding Division.

Lieut.-Col. H. L. de Legh resigns his commission, and retains the rank of Lieutenant-Colonel, with permission to wear the prescribed uniform.

Capt. A. M. Baillie resigns his commission and retains his rank.

J. A. L. Louden to be Lieutenant.

Capt. R. Ellis resigns his commission and is granted the rank of Major.

Supernumerary for Service with the O.T.C.: Major H. Emerson (late R.A.M.C.) to be Captain, for service with Belfast University Contingent, Senior Division, O.T.C., and to relinquish the rank of Major.

Capt. H. Emerson to be Major.

2nd London Sanitary Company: Capt. F. S. Carson resigns his *commission and retains the rank of Captain.*

The King has conferred the Territorial Decoration upon the undermentioned officers:—

Army Medical Service.—Col. A. D. Sharp.

Royal Army Medical Corps.—Lieut.-Cols. T. Donovan (1st Welsh Field Ambulance), A. Callam (2nd East Lancashire Field Ambulance), R. W. Brimacombe (Home Counties C.C.S. (ret.)); Majors L. A. Avery (East Anglian Division), J. Owen (attached Lan. Fort. R.E.), G. Mackie (1st S. Middlesex Field Ambulance), W. G. Paget (attached 4th Bn., The Queen's Regiment), C. A. Spooner (2nd London Sanitary Company).

ROYAL AIR FORCE.

Medical Branch.—The undermentioned are granted temporary commissions in the ranks stated:—Flight Lieutenants: D. Le Bas and W. R. Reith. Flying Officer: J. A. Perdrau.

INDIAN MEDICAL SERVICE.

Lieutenants to be Captains: Bager Zainulabiedin Shah, Prabodh Chandra Banerjee, Bishambhar Sahai.

The King has approved the admission of the following as Captains: C. Burnham, J. J. Rooney, and P. H. S. Smith.

The undermentioned have relinquished their commissions and rank has been granted as shown: Temp. Capt. Ram Nath Sharma, Temp. Capt. Maung Ba Yin, Temp. Capt. Kantilal Kalynji Mankodi, and Temp. Capt. Vinculathoor Ramasami Sundaresan. And are granted the rank of Captain on relinquishing their temporary commissions: Sita Nath Ghosh, Aaron Joseph, Umedram Lalbhai Desai, Homi Shivax Dastur, Vasudeo Gopal Bhandare, and Ram Narain Sad.

The King has given orders for the following appointments:—

Most Excellent Order of the British Empire.—To be Members of the Civil Division: Dr. Subramanyam Yenamundram, Civil Surgeon, Upper Chindwin, Mawlaik, for services during minor operations in Burma and Persia; and Miss Sheerburn, M.B., B.S., for services during the operations against Afghanistan.

The King has granted unrestricted permission to the undermentioned to wear the Cross of Chevalier of the Legion of Honour conferred upon them by the President of the French Republic in recognition of their services to the French sick and wounded at Hôpital bénévole, No. 115 bis, at Villeneuve-sur-Lot during the late war: Dr. W. R. Dakin, Dr. F. M. Graham, and Dr. A. K. Henry.

Obituary.

ROBERT MURRAY LESLIE, M.D. ED., M.R.C.P. LOND.

THE unexpected death, at the comparatively early age of 55, of Dr. Robert Murray Leslie will be keenly felt by a wide circle of friends, medical and lay. For the past few months his health had failed, and he had on that account just resigned the position of senior physician to the Royal Chest Hospital. Dr. Leslie came of an old Scottish Highland family, being the son of the late Alexander Leslie, J.P., of Suddie, Munlochie, Ross-shire, and one of six brothers, four of whom entered the medical profession. He received his schooling at George Watson's School and at the University of Edinburgh, in which he graduated M.A. in 1888, B.Sc. in 1889, and M.B. in 1892, in each case with first-class honours. In science and in medicine he was the most distinguished graduate of his year, being awarded the Baxter and the Ettles Scholarships in these faculties respectively. After graduation he became house physician to the late Sir Thomas Grainger Stewart, and, while Stark scholar in clinical medicine, he worked in the laboratory of the late Professor Greenfield, whom he assisted for a short time in the pathological department of the University. Migrating to London soon after, he held many hospital and other medical posts, including a house physicianship at Brompton and the medical registrarship at King's College Hospital. At the time of his death he was still senior physician to the Prince of Wales Hospital, in the development of which and of the North-East London Post-Graduate College he had played no small part, and he had just surrendered a similar position at the Chest Hospital, the amalgamation of which with another hospital, and the consequent loss of its traditions and identity as the oldest hospital for diseases of the chest in the world, he keenly regretted. Dr. Leslie was an excellent lecturer and teacher; he also contributed widely to medical literature, including child welfare and eugenics, a volume on Pneumonia and its Modern Treatment, to which he had given much thought and attention, being ready for the press. He was widely recognised as a consultant upon diseases of the chest, and his hospital colleagues will miss a loyal and generous personality, whose services were ever freely at their disposal. His interest in the nursing profession was very keen, and his work for child welfare, especially in the form of travelling exhibitions, had made him a prominent member of that movement. His own love of travel was highly developed and he was an enthusiastic mountaineer. A distinction he greatly valued was that of officer of the French Academy.

A few years ago Dr. Murray Leslie founded a medal in Edinburgh University, in honour of his mother, the foundation being suggested by the fact that three of her four medical sons were graduates of the University. To her and to his widow, daughter of Captain Knox Keith, R.N., the sympathy of the medical profession will go out.

THE LATE DR. W. F. CROSSKEY.—Dr. Walter Francis Crosskey died at Lewes, his native town, on March 29th, after a few days' illness. Born in 1843, he studied at Glasgow University, and took the M.D. and C.M. degrees in 1865. He practised in Lewes for 30 years, holding a number of public appointments, and retired in 1912. He took a prominent part in local affairs and was the second mayor of the borough—in 1882–83. He was placed on the Commission of the Peace in October, 1909. He married in 1872, and his wife survives him.

"Audi alteram partem."

LEUCOCYTOLYSIS IN TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—The claims made in Dr. Ivan I. Manoukhin's interesting article in your last issue are not new in the realm of tuberculosis, for lysis of leucocytes in the affected area in the lungs appears to be what occurs after the exhibition of tuberculin. But one would have liked to know more of the after-history of the 8000 cases of pulmonary tuberculosis personally treated by the author. Dr. Manoukhin regards the treatment as inapplicable only in cases of extreme exhaustion accompanied by a vigorous intoxicative affection of the blood-forming apparatus. What form of tuberculosis of the lungs with any degree of activity is not associated with such a toxic action? Where there is also lysis of the tuberculous area, antigen is set free and interaction in the blood is enhanced, while no one can tell where the process will stop. One would imagine, therefore, that the 8000 were cases where the colloids of the blood had not been impaired to any extent, corresponding to our cases with early hæmorrhage and an infiltration of an apex. The reaction might then be regarded as a greater extension of the auto-inoculation complex of Marcus Paterson. To generalise in tubercle from one race to another may lead to mistaken conceptions of therapeutic value. Possibly a Russian, and especially a Russian Jew, would stand this treatment, while in a negro, or a North American Indian, a miliary spread might result.

On the other hand, artificial pneumothorax therapy, by collapse of the lungs, shortens the lines of attack and conserves the leucocytes, improves and maintains the colloids of the blood, and although it does not make for rapid cure, follows very closely nature's method. Then there are the two types of therapy, and it will probably be found later on that the truth lies between them.

Most of our own race appear able to handle the infection of tubercle by themselves. Irradiation of the spleen will in the main help those cases in which the lymphatic tissue is involved, but in which the coagulability of the blood is normal and the white cells are not changed to any degree. In America, and especially in the West, electrical treatment of enlarged prostate, strictures, and even of cancer, by means of lysis, has been the fashion for a long time. Here we have not forgotten the days of Coley's fluid. And in tuberculosis many cures probably have their origin in this process of increased katabolism. Increase the antibody, there will be fibrotic change somewhere.

To sum up, the processes through which the tuberculous patient passes are these:—

1. Sensitisation, with disease limited by lymphatic tissues, blood normal, especially coagulability.
2. Hyper-sensitisation with spreading disease, marked hypocoagulability, great strain on leucocytes.
3. Often a rapid change to fibrosis, with normal or plus coagulability and less strain on the leucocytes, the disease is beaten, the patient desensitised; often, however, he is left with sequelæ by no means comfortable, dyspnœa, and tendency to cardiac failure.

In process of curing tubercle nature has to adapt herself slowly to changing conditions. Furthermore, in infections where immunity is gained in a relatively short time the leucocytes rapidly provide by phagolysis the adequate plasma, as in croupous pneumonia, and this is followed by fibrinolysis soon after defervescence. In active pulmonary tuberculosis, however, the two processes of phagolysis and fibrinolysis seem to be concurrent. The balance between them appears connected with the line-up of the leucocytes in the morbid lung. In watching the formation of clots where fibrin formation is poor the larger leucocytes appear, owing to their greater stickiness, to form up in line, while the reds pass through unhindered, the lymphocytes tending to crowd in towards the centre of the coagulum, owing to retraction of the fibrin. Does this occur in a pathological state? The basophil elements seem to be in great demand, and in sputum the lymphocyte predominates, pointing to a greater mobility on its part, in that the lymphocyte gets right into the centre of the necrotic area, which will be softened and discharged.

It takes a case of pulmonary tuberculosis, where there is any active softening disease, months so to adjust the materials in the blood that it can carry on the processes of holding the enemy, and reinforcing itself behind the lines. Can radiation of the spleen help this? Certain cases may respond to more radical methods, but in the main we cannot afford to discard the older conservative principles.

I am, Sir, yours faithfully,
J. J. THOMSON, M.B.,
Senior Assistant, Middleton-in-Wharfedale Sanatorium.
Ilkley, April 2nd, 1921.

ANALYSIS OF THE GASTRIC CONTENTS.

To the Editor of THE LANCET.

SIR,—I apologise to Dr. W. J. Adie and Mr. S. W. Cole for giving the old end-point for thymol-blue at $HCl.N \times 10^{-2\cdot6}$ instead of that proposed by them—namely, $HCl.N \times 10^{-2}$. There are two reasons for retaining dimethyl as an indicator: one is that data have been accumulated with its use; the other that it gives information of the degree of acidity of the material when that acidity, though considerable, is not high enough to affect thymol-blue. As I stated in my paper (THE LANCET, March 19th), the term "free HCl" applied to dimethyl titration is a misnomer. I think the best plan would be to use both indicators. The meaning of the term "free HCl" would not matter provided a reasonable measure of the concentration of hydrogen-ions in test-meals were so obtained, not only in those where the hydrogen-ions happen to be high.

I am, Sir, yours faithfully,
Guy's Hospital, S.E., April 4th, 1921. J. H. RYFFEL.

A CONTROLLED STUDY OF SANATORIUM RESULTS.

To the Editor of THE LANCET.

SIR,—With reference to Dr. E. Ward's article on the results of sanatorium treatment in your issue of March 12th it has occurred to me that perhaps Dr. Ward and also Dr. T. Campbell and Dr. J. Crocket may be correct in what they state. It seems clear that, whatever Dr. Ward's statistics may be worth, he himself is not satisfied with the results in cases which he has sent to sanatoriums. If the results had been in any way encouraging he would doubtless have observed this. The confusion of results probably depends on the application of the term sanatorium treatment. It is generally assumed that all institutions which are labelled as sanatoriums are the same, and carry out the same treatment. This is, of course, a fallacy, for so far as my knowledge goes, only a few sanatoriums use rest as the main form of treatment, and only a few trouble to take rectal temperatures. A large number have no resident medical superintendent, and doubtless a number have superintendents who have never learnt the elements of treatment.

We find here that on the whole almost all the patients improve, and that early cases get well to the extent of 70 per cent., medium cases show a percentage of 45 per cent., whilst what are usually described as third stagers remain well in 12 per cent. of cases. I quite agree with Dr. Ward that graduated labour as such should be abolished from sanatoriums, with this proviso, that, when afebrile, the patients should be given as much exercise and work as possible without provoking obvious auto-inoculation.

I notice Dr. Ward did not send some cases because of the stigma attached to going to a sanatorium; of course, if this idea is allowed to pervade our thoughts when dealing with these patients, it becomes impossible to treat cases so that they can be cured in a reasonable time; in addition, a vicious circle is formed, as very poor results will be obtained at the sanatorium, with the result that most persons observing the fatal tendency of sanatorium cases will prefer to remain unnotified until they cannot escape. If cases are treated sufficiently late, then whatever treatment is adopted the results will be similar, ending in the death of the patient. I remember some years ago visiting the dispensary of one of my late assistants; among other things he showed me four or five patients which he had sent away to the sanatorium, and explained to me they had all come back worse, and, as he said, they would have done better at home. I asked him if this kind of thing occurred at the Ayrshire Sanatorium, and he replied that it did not. The first essential for a sanatorium is that cure should be aimed at and not palliation, all dodges for propping up patients should be eschewed: the idea getting abroad that if you go to a sanatorium you will thereafter be only able to lead some kind of maimed existence is absolutely discouraging.

The methods at sanatoriums should be inquired into, and it should be arranged in all, that at long last, they shall be used for early cases, and that the cases shall get the treatment which they require and be given the requisite amount of rest necessary, as estimated by the study of a correctly kept temperature chart. Further, neither work nor occupation nor amusements should be allowed to interfere with the progress of these cases to complete recovery. It was a tragedy, that when it was discovered that pulmonary tuberculosis, like surgical tuberculosis, is best treated by rest, and when sanatoriums were provided to carry out this purpose, then the practice was instituted of working these patients, who should have been in bed, with the lamentable result that we have depicted in Dr. Ward's paper.

I am, Sir, yours faithfully,
EDWARD E. PREST.
Ayrshire Sanatorium, New Cumnock, April 4th, 1921.

BACTERIOLOGY IN THE CURRICULUM: A CORRECTION.

To the Editor of THE LANCET.

SIR,—In reference to the report of the discussion at the Society of Medical Officers of Health, which appears in your issue of to-day's date, I fear I must have given a wrong impression in what I said concerning the late Dr. Washbourn's successful advocacy of the inclusion of bacteriology in the curriculum for medical students. I took no part in the matter. The credit belonged to him, and so far as I know, almost entirely to him.

I am, Sir, yours faithfully,
Hampstead, April 2nd, 1921. E. W. GOODALL.

A DISCLAIMER.

To the Editor of THE LANCET.

SIR,—There have recently appeared in the lay press articles which purport to be abstracts of a paper recently read by us at the Royal Society of Medicine on a new anæsthetic. These were published entirely without our knowledge or permission.

We are, Sir, yours faithfully,
R. L. MACKENZIE WALLIS, M.D.
April 8th, 1921. C. LANGTON HEWER, M.B.

THE DIPHTHERIA SWAB ON DISCHARGE.

To the Editor of THE LANCET.

SIR,—In the report of the meeting of the Society of Medical Officers of Health on "Relation of Laboratory to Preventive Medicine" given in THE LANCET last week, it is to be observed that several of the speakers seemed to consider that no swab should be taken from diphtheria cases on discharge from hospital. I have in mind two instances recently, one fatal, which were associated with the insufficient taking of swabs. The first was a boy treated at home in whose case a negative swab from the nose was obtained on one occasion; unfortunately swabs both from the nose and throat were in consequence not taken consistently. To put the matter more clearly, a swab was taken both from the nose and the throat, the swab from the throat was positive, the one from the nose negative. In consequence, next time the child was swabbed no examination was made of the nose. When the throat swab proved negative the boy was released from isolation, but unfortunately his brother contracted the disease. Swabs were again taken of the first patient, with the result that the nose proved to be harbouring diphtheria bacilli. The brother unfortunately died. In the second instance the disease was introduced into a family by a boy sent home from boarding-school after an attack of diphtheria. Apparently swabs had only been taken of the throat. Shortly after his arrival home another child in the family was affected, and on swabs being taken from the convalescent patient the organism was found to be present in the nose.

Another point of interest was the remark of the President that the medical officer of health could spend his time most profitably in administrative work, and that he should not devote himself very much to laboratory work. Why should not a member of the staff of the medical officer of health carry out such bacteriological work with advantage to the community?

I am, Sir, yours faithfully,

April 2nd, 1921. M.O.H.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Changes at the Ministry of Health.

As a result of the changes which have been made in the personnel of the Government, Dr. ADDISON has retired from the office of Minister of Health, but remains a member of the Cabinet as Minister without Portfolio. Dr. ADDISON, since he entered Parliament as Member for the Hoxton Division of Shoreditch in 1910, has taken a special interest in legislation dealing with health matters, and was prominently associated with the passing of the Insurance Act. In 1919 he was appointed the first Minister of Health on the formation of a new department to take the place of the Local Government Board, and to take over certain powers formerly exercised by other Departments of State. He was the Minister in charge of the Ministry of Health Act during its passage through the House of Commons. He is succeeded as Minister of Health by Sir ALFRED MOND, who has for some time been the First Commissioner of Works.

HOUSE OF COMMONS.

MONDAY, APRIL 4TH.

Scottish Board of Health Report.

Mr. MORISON (Lord Advocate) informed Dr. Murray that it was expected that the annual report for 1920 of the Scottish Board of Health would be published in the course of the present month.

TUESDAY, APRIL 5TH.

Bradford Corporation Hospital.

Mr. GEORGE THORNE asked the Minister of Health the present position in regard to the acquisition of a Poor-law infirmary by the Bradford corporation, to which he at one time gave his sanction, which was afterwards withdrawn.—Sir ALFRED MOND replied: Provisional sanction was given to the scheme in June last, and this has never been withdrawn. But before giving a final decision I urged on the council the importance of full consultation with the medical profession in Bradford. As a result of this a local Advisory Medical Committee was appointed, and this committee has put forward certain suggestions which are being considered by the council, from whom I am expecting to hear shortly.

Superannuation of Local Government Board Officers.

Mr. ARTHUR HENDERSON asked the Minister of Health whether, in view of a statement made by him to a deputation from the Association of Municipal Corporations on the subject of the superannuation of Local Government officers, it was proposed to introduce the Bill this session and pass it into law.—Sir ALFRED MOND replied: The Government regret that they cannot proceed with this matter at the present time in view of the heavy charges which the scheme would impose upon the rates.

Medical News.

UNIVERSITY OF DURHAM.—At the Convocation held on March 26th the following degrees were conferred:—

Doctor of Medicine for Practitioners of 15 Years' Standing.—Charles Corfield and Richard J. C. Thompson.
Master of Surgery.—James A. Berry, William A. Hewitson, and Norman Hodgson.
Bachelor of Medicine and Bachelor of Surgery.—James S. Clark, Robert C. Davison, Thomas W. K. Dunscombe, Norah H. Hamilton, Robert T. E. Naismith, Joseph D. Silverston Thomas S. Severs, Habib Toma, and Robert P. Wanless.
Bachelor of Surgery.—Margaret B. Herbst.
Bachelor of Hygiene.—William L. Glegg.
Diploma in Public Health.—William L. Glegg.
Licence in Dental Surgery.—Fred Wilkinson.

UNIVERSITY OF ABERDEEN.—The following degrees have been conferred:—

DOCTOR OF MEDICINE.

James B. Milne.

BACHELOR OF MEDICINE AND BACHELOR OF SURGERY.

Charles D. Allan, John J. H. Anderson, *Nicholas C. Bodenstein, Foong Kong Chen, *John Craig (second-class honours), Lilian F. Gall, Ronald K. Grant, George G. W. Hay, *Eleanora M. P. Law (second-class honours), Margaret Lipp, *Matthew H. Logg, *Douglas R. Macdonald (second-class honours), Alexander MacKay, Elsie Mackie, Katharina F. E. van der Merwe, Mary G. Milne, D. Mitchell, John I. Moir, Marion E. Mowat, Isabella M. H. Murray, *Janet C. Nicol, *Mary M. Pyper (second-class honours), Alexander E. Reid, Edwin N. D. Repper, *James P. J. Rossouw, George Saint, Norman C. Simpson, Ethel V. G. Smith, Ian R. Spark (second-class honours), *Alexander L. G. Thomson, Ian S. Thomson, and Alexander R. Wood.

* Passed Final Medical Professional Examination with distinction.

DIPLOMA IN PUBLIC HEALTH.

Douglas W. Berry, Alexander M. Dugan, Francis A. Innes, Harry R. Neilson, William W. Nicol, James A. Sellar, and Agnes L. Semple.

UNIVERSITY OF DUBLIN, SCHOOL OF PHYSIC, TRINITY COLLEGE.—At examinations held recently the following candidates were successful:—

INTERMEDIATE MEDICAL EXAMINATION.

Part I., Anatomy, Physiology, and Organic Chemistry.—Robert F. J. Henry (high marks), Ernest M. Landau (high marks), Louis E. J. Werner (high marks), Reginald R. J. Brandt (high marks), Morris Cohen and George Robinson (equal), Etienne R. Hafner, Harold Renton, Samuel M. Geffen and Joseph Morris (equal), Charles W. J. Ingham, John L. Stuart, Jack A. Levitt, Solomon Narunsky, Victoria J. Wilson and Albert V. Wood (equal), Gerard A. A. Powell, John G. Maguire, Herbert Birney, Francis V. Duke and George R. L. Jordan and James L. Marshall (equal), Dorothy J. Booth and Alexander Hawthorne (equal), Norah M. Smith, and Israel Marin and Robert Y. Crichton (equal).
Anatomy only.—Tobias Freedman, Cecil McQuillan, James Craig, Eileen Brangan, John S. Glasgow.
Part II., Applied Anatomy and Applied Physiology.—Agnes McLaughlin (high marks), Bernard Gluck (high marks), Robert H. Micks (high marks), Joseph A. Gaynor and Robert T. Jackson (equal, high marks), William F. Whaley (high marks), Francis J. O'Meara (high marks), Florine I. Irwin, Eric C. Downer and Ernest M. Landau (equal), Anthony B. Monks, Lazarus Heyman, William E. Hutchinson and David J. Malan (equal), Bernard Morris, Reginald Hegy and Marjorie F. Sibthorpe (equal), Cecil A. V. Ovendale, Benjamin W. D. Fayle and Dermod H. F. Milmo (equal), Ely G. Copeland, John C. Earl and George F. T. Saunders (equal), Wilfrid E. C. Wynne, Percy Samolsky, Arthur Darlington, Henry M. Martin, Etienne R. Hafner, James E. Deale, Frederick G. Brown and James O'Neill McKenna (equal), Douwe M. Vellema, Louis J. Coetzee and Cecil G. S. Van Heyningen (equal), Alice M. A. Downing and Richard C. L. Griffiths (equal), Max Wulfsohn, Reuben Lipschitz, Mossy Jaffe, Norman E. H. P. Williams, Asher Asherson and Philipp F. H. Wagner (equal), William S. Dixon and Thomas G. Wilson (equal), Hans J. Hugo and Raymond J. G. Hyde (equal), John D. Wicht, Herbert Rollins and Maria E. Wagener (equal), Frederick W. G. Smith and Isabella H. Speedy (equal), Michael Gallivan, Charles T. MacCarthy, Harold Lewin, Alexander Bernstein, Robert L. C. Fisher, Lionel S. Levitt, Victor O. McCormick and Jan H. Rauch (equal), James J. Fitzgerald, Edward Harvey, John Kalmanson and Julius Kruger (equal), and Charles Gordon.
Applied Anatomy only.—Mary E. Hardy.

FINAL MEDICAL EXAMINATION.

Part I., Materia Medica and Therapeutics; Jurisprudence and Hygiene; Pathology and Bacteriology.—Leopold Stazunsky (high marks), Allen L. Drotske (high marks), Francis C. B. L. R. Crawford (high marks), David S. Spence, John V. Carroll and Robert A. O'Meara (equal), Minnie Alper, Richard Seale, Charlotte A. Stuart, John D. Watson, Francis B. D'Arcy and Ruth Lemon (equal), Cecil W. R. McCaldin, Francis Malone-Barrett, Petrus H. S. Fouche, Joseph E. Deane and Joseph O'Connor (equal), Henry J. L. Murphy, Max Sayers, John G. Russell, Donald H. Saayman, Dorothy O. H. Dornan, Muriel V. Odlum, Mary H. Harcourt, Laurence Phillips, Izidore P. Myers, and Joseph C. Byrne.
Materia Medica and Therapeutics; Jurisprudence and Hygiene.—Herbert Hall and William T. Hogan.

Jurisprudence and Hygiene; Pathology and Bacteriology.—Robert N. Perrott.

Pathology and Bacteriology.—Arthur G. Bewley, Ninian McI. Falkiner, and Albert E. Phillips (equal), George S. Moran, Henry L. Hanna, Harry C. Dundon, James J. P. Kelly, and James Devane.

Part II., Medicine.—James A. Smith, David J. Browne, Robert H. J. M. Corbet, Thomas F. L. Cary, and Elinor D. Stopford (equal), Hector C. C. Deane, Edith F. Willock, Francis Y. Pratt, and Robert H. Satchwell (equal), Dorothy A. Daly, Cecil S. Wilson, Eric S. Horgan, Ruth F. Flavelle and Donald V. Latham (equal), Robert S. Chapman, James A. Acheson, Patrick M. J. Bobbett, Richard W. Power, Thomas W. Panter, James D. Leahy, James C. Davis, Anthony D. Ward, and Patrick Joseph Healy and George Cyril Brereton Robinson (equal).

Surgery.—Edmund C. Smith (high marks), Daniel de Bruijn, Richard V. Dowse and James D. Leahy (equal), Hector C. C. Deane, William H. Smith and Margaretta T. Stevenson (equal), Dorothy A. Daly, Leo Herzenberg, Robert S. Chapman, Percival I. Levitt, Gideon C. Malherbe, Patrick J. Healy and *Charles W. Parr (equal), James A. Acheson*, John C. Brennan, Francis M. Hilliard, Alida C. Burt and Edward G. Campbell (equal), and Mary Horan and Robert H. Satchwell (equal).

Midwifery.—Anthony D. Ward (high marks), Eric R. Murray (high marks), Robert H. J. M. Corbet (high marks), Michael R. Coolican and Nannette Norris (equal, high marks), Alfred H. N. *Todd, Leo Herzenberg, William A. Murphy, Robert Dormer*, John D. Thompson, Thomas G. Warham, Alida C. Burt and Robert S. Chapman (equal), and Rita Dillon-Leetch and Eric S. Horgan (equal).

INTERMEDIATE DENTAL EXAMINATION.

Anatomy and Physiology.—John H. B. Tuke and Robert H. McKeag.

DIPLOMA IN PUBLIC HEALTH.

Part I., Chemistry, Bacteriology, Physics, and Meteorology.—Thomas J. KilBride, Thomas P. Chapman, Thomas D. Gordon, and Hilgard Muller.

Part II., Sanitary Engineering, Sanitary Inspection and Report, Hygiene, Epidemiology, Vital Statistics, and Public Health Law.—Thomas J. KilBride, Hilgard Muller, Thomas P. Chapman, and Thomas D. Gordon and Anna M. K. O Halloran (equal).

HARVEIAN SOCIETY.—A meeting of this society will be held at the Town Hall, Harrow-road, Paddington, on Thursday, April 14th, at 8.30 P.M., when Mr. Duncan Fitzwilliams will give a paper on the Nævi of Children and their Treatment.

CHARTERED SOCIETY OF MASSAGE AND MEDICAL GYMNASTICS.—The annual meeting of this society will be held on Saturday, April 16th, at 3 P.M., at the Armitage Hall, 221, Great Portland-street, W. Among the subjects to be discussed are an insurance scheme for registered members, Red Cross clinics and civilian patients, and a proposed club for professional women.

SOCIETY OF MEDICAL OFFICERS OF MATERNITY AND CHILD WELFARE CENTRES.—A meeting of this society will be held on Friday, April 15th, at 5.30 P.M., in the Central Committee Room, University College, Gower-street, London, W.C., when a paper will be read by Dr. Marion Cockerell entitled "Infant Feeding after the Ninth Month." A discussion will follow. Members are invited to bring friends provided that they are officers of centres.

POST-GRADUATE COURSE ON MENTAL DEFICIENCY. A course of post-graduate lectures on Mental Deficiency with clinical instruction has been arranged by the University Extension Board of the University of London in coöperation with the Central Association for the Care of the Mentally Defective. The course will begin on Monday, May 23rd, and end on Saturday, June 4th; it is intended for qualified medical practitioners, and more especially for those who are engaged as certifying officers to local authorities under the Mental Deficiency Act, 1913, as school medical officers, or as medical officers of institutions, or who are otherwise definitely concerned with defectives. The course is based on the requirements of the syllabus for the University of London Diploma in Psychological Medicine, and the University will grant a certificate of attendance to those who have attended the whole course regularly, taking both theoretical and practical work. The syllabus includes 11 lectures on Mental Deficiency by Dr. A. F. Tredgold, five lectures on Administrative Procedure in the Ascertainment and Treatment of the Mentally Defective by Dr. F. C. Shrubsall, and three lectures on the Psychology of Mental Defectives by Mr. Cyril Burt, psychologist to the L.C.C. Miss Lucy Fildes, B.A., holder of Board of Control Research Studentship at the Psychological Laboratory, Cambridge, will give two lectures on Methods of Training Mentally Defective Children. Dr. Eric Prideaux will lecture on Psychoneuroses in Relation to Mental Deficiency, and Dr. W. C. Sullivan on the Relationship Between Crime and Mental Defect. In addition demonstrations and visits to schools and institutions will be arranged. The registration fee is £1 1s., and the fee for the course £5 5s. Applications d all communications with reference to the course should addressed before May 2nd to Miss Evelyn Fox at the versity of London, Imperial Institute-road, South ington, London, S.W. 7.

Mr. Alexander Thomas Scott, *M.B.E.*, M.R.C.S., has been appointed an Esquire of the Order of St. John of Jerusalem in England.

MEDICO-LEGAL SOCIETY.—A meeting of the society will be held at 11, Chandos-street, London, W., on Tuesday, April 19th, at 8.30 P.M. A paper will be read by Mr. W. G. H. Cook, *on the Liability of the Insane in Respect of Civil* Wrongs.

SOCIETY FOR THE STUDY OF INEBRIETY.—The annual meeting of the society will be held in the rooms of the Medical Society of London, 11, Chandos-street, Cavendish-square, W., on Tuesday, April 12th, at 4 P.M., when Dr. H. H. Dale, F.R.S., will open a discussion on the Use of Alcohol in Medicine. Each member and associate is at liberty to introduce visitors. Subscriptions for the session 1921-22 were due on April 1st, and should be forwarded to the honourable treasurer, Mr. Arthur Evans, M.S., F.R.C.S., 28, Devonshire-place, London, W. 1.

HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET: NURSING STAFF SALARIES.—The following scale of *nursing staff salaries has been adopted by the Committee of* Management: Matron, £275, annual increment £10 to £350; assistant matron, £100, annual increment £10 to £140; home sister, £90, annual increment £10 to £130; night sister, £85, annual increment £10 to £125; ward sisters, £80, annual increment £5 to £120; *staff nurses, £50, annual increment* £5 to £60; probationers, first year, £20; second year, £25; third year, £30; all to be retrospective to Jan. 1st, 1921.

LONDON AND COUNTIES MEDICAL PROTECTION SOCIETY.—The report of the Council of the society, which was presented at the annual meeting held at the offices, 22, Craven-street, Strand, on April 6th showed a very satisfactory year's working in 1920. The temporary check to membership on account of the war has now abated and during the year under notice 733 new members were added to the roll, while 69 members died and 190 withdrew. The total membership on Dec. 31st, 1920, amounted to 6162. The funds of the society have increased from a surplus balance of £25,825 11*s.* 1*d.*, shown on the balance-sheet for the year ended Dec. 31st, 1919, to a balance of £26,168 19*s.* 11*d.*, shown on the corresponding date at the end of 1920.

DONATIONS AND BEQUESTS.—By the will of the late Miss Blanche Elizabeth Pinnock, of Oakdene, Caldy, Cheshire, the testatrix, among other bequests, left £1000 each to the Sir Alfred Jones Memorial Hospital, Garston; the Convalescent Home for Children, West Kirby; and the Home for Epilepsy at Maghull.—The late Mr. John Padbury Gillett, of Banbury, left by will £200 to the Horton Infirmary, Banbury; and £100 to the Society for the Prevention of Cruelty to Children.—By the will of the late Mrs. Georgina Ann Birks, of Kingsbridge, Devon, the Hospital for Women, Soho, will benefit by £500.—The late Miss Gertrude Agnew, of Pendleton, Manchester, left by will £1000 each to St. George's Hospital, London; St. Mary's Hospital, Manchester; the Manchester and Salford and District Branch of the National Society for the Prevention of Cruelty to Children.—Under the will of the late Mrs. Lucy Elizabeth Dangerfield, of Eastbourne, the testatrix left, on the failure of certain trusts, £1000 to the Princess Alice Hospital, Eastbourne, for a "Tate Dangerfield" bed; £500 to St. Dunstan's Hostel; and £500 to the National Institute for the Blind.

FEDERATION OF MEDICAL AND ALLIED SOCIETIES (INC.).—At a meeting of the Exective Council of the Federation held on April 5th it was announced that its incorporation had been satisfactorily completed. Sir Berkeley Moynihan was elected the first president and Sir Malcolm Morris, the chairman of Council, was elected vice-president. In view of the increasing activities of the Federation, and in accordance with its Articles of Association, the Executive Council now delegates the control of its various sections to the following branch councils: (1) a Medical Council, (2) a Council of Allied Professions, and (3) a Citizens' Council. Each society is now to have a representative on the Council appropriate to its professional interests. These councils will meet quarterly as the Executive Council, and at other times in joint conference.

It is anticipated that the offices will be transferred to more suitable premises at a very early date, where it will be possible to provide the constituent societies with a conference hall and certain secretarial and other advantages. Current literature dealing with the public aspect of medicine is also always to be available.

The meeting had many matters under its consideration, including reports as to recent action undertaken on behalf of the societies in regard to the Dangerous Drugs Act Regulations and the change of Minister at the Health Ministry. The British Association of Radiology and Physiotherapy was elected to membership.

THE mail service with Russia reopened on April 7th at the usual continental rates of postage.

LITERARY INTELLIGENCE.—Messrs. Putnam announce for immediate publication "The Psychology of Nursing," by *Aileen Cleveland Higgins.*

SOCIETY FOR THE PREVENTION OF HYDROPHOBIA.—A meeting of the committee of this society was held on Monday, April 4th, at the Royal Society of Medicine. In the course of a discussion with regard to rabies, Mr. F. W. Fletcher stated that the authorities at the Board of Agriculture considered the official action already taken to be sufficient to control any recurrence of the outbreak of 1918. The last proved case of the disease occurred in Buckinghamshire during January, 1921. The greatest care, he said, was exercised by Customs officials at ports and aerodromes, but pet-dogs had probably been introduced into the country in a drugged condition. He pointed out that the existing muzzling order sometimes left unprotected districts islanded by scheduled areas, while dog-owning magistrates might be too lenient in the interpretation of their powers. Major Penberthy, *from* the chair, said that during one year in the history of the society about 700 cases of hydrophobia had occurred in England and Wales, and contrasted this state of affairs with conditions obtaining at the present time, observing that no cases of hydrophobia had been reported during the recent outbreak of rabies. A resolution was unanimously carried in support of legislation to amend the Diseases of Animals Act (1894), by which the contravention of any muzzling order in force shall be rendered punishable by imprisonment without option of a fine.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Monday, April 11th.

An interesting Demonstration of Lantern Slides in Natural Colours of Dermatological and other Medical Subjects will be given at 5 P.M., and all Fellows and Members of Sections interested in the subject are cordially invited, as it is a new method (*"Uvachrome") in colour production, requiring no "screen"* on the slide.

Tuesday, April 19th.

GENERAL MEETING OF FELLOWS: at 5 P.M.
Ballot for Election to the Fellowship.

MEETINGS OF SECTIONS.

Monday, April 11th.

WAR SECTION: at 5.30 P.M.
Paper:
Surg.-Commdr. S. F. Dudley, R.N.: A Few Observations on the Influenza Epidemic as it Affected the Royal Navy.

Wednesday, April 13th.

SECTION OF SURGERY: SUBSECTION OF PROCTOLOGY: at 5 P.M.
Discussion:
On "Pruritus Ani," to be opened by Mr. Lockhart-Mummery and Sir Charles Gordon-Watson.

SECTION OF SURGERY
SECTION OF DERMATOLOGY
Members of these Sections are cordially invited to attend the above Meeting.

Saturday, April 16th.

SECTION OF OTOLOGY, at the Leicester Infirmary; at 2.30 P.M.
Papers:
Mr. T. B. Layton and Mr. Archer Ryland: The Quantitative Estimation of Hearing, with Special Reference to Unilateral Deafness.
Mr. F. J. Cleminson: Sinusitis in Children.
Cases will be shown by Dr. Macleod and Mr. Keen.
There will also be a Demonstration at the Aural Clinic of the Leicester Education Committee.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.
MONDAY, April 11th.—8 P.M., Cantor Lecture (I.):—Dr. S. J. Lewis: *Recent Applications of the Spectroscope and the Spectrophotometer to Science and Industry.*
WEDNESDAY.—8 P.M., Prof. H. E. Armstrong: *Low Temperature Carbonisation and Smokeless Fuel.*

HARVEIAN SOCIETY OF LONDON, at the Town Hall, Paddington Green, W.
THURSDAY, April 14th.—8.30 P.M., Paper:—Mr. D. C. L. Fitzwilliams: The Naevi of Children and their Treatment.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.
Museum Demonstrations in the Theatre of the College for Advanced Students and Medical Practitioners:—
FRIDAY, April 15th.—5 P.M., Prof. Keith: *Specimens illustrating* the Comparative Anatomy of the Cæcum, Appendix, and Great Bowel.

Notes, Short Comments, and Answers to Correspondents.

PUBLIC HEALTH IN BOMBAY, 1919.

IN the introductory remarks to his first annual report on the administration of public health in Bombay for 1919, Dr. J. E. Sandilands, who took over the duties in February, 1920, states that it is, in fact, the report of Dr. Sorab C. Hormusjee, who was in charge of the department from April 27th, 1919, when Dr. J. A. Turner (author of the well-known treatise on "*Sanitation in India*") proceeded on leave, pending retirement, after having served as executive health officer since February, 1901. The conditions of public health during the year were far from satisfactory: there were epidemics of cholera, small-pox, plague, and influenza, though much milder (except in the case of cholera) than in 1918. It has to be borne in mind that the ratios for disease prevalence and death are still calculated on the census enumeration of 1911 (979,445), though the increase since then, owing to natural as well as adventitious causes, has been estimated at not less than 200,000. The birth-rate, as calculated in the usual way, was 21·16 per 1000 of the total population, representing 20,730 births; but if adjustment be made for children vaccinated, whose births had not been registered, and for a (presumed) similar unregistered proportion who escaped vaccination, a ratio of 21·71 per 1000 is obtained (representing 27,114 births) which is perhaps an approximation to accuracy as near as can be obtained. For the Hindu communities as a whole, who form the majority of the population, the ratio was 20·54; ranging from 11·35 among Brahmins to 60·88 among Hindus "of low caste," and 89·83 among Lingaits. For Mussulmans and Negro-Africans it was 21·00; for Indian Christians, 26·99; for Europeans, 12·02. As compared with 1918, the general birth-rate was slightly lower, 21·16 against 22·18 per 1000. There were, as usual, very wide variations in different parts of the city, though it is pointed out that these may be largely accounted for by the uneven distribution of women and married women of fertile age. The highest ratio was recorded in Upper Colaba section (50·09), which was, however, not so high as that of the preceding year (55·87); the next highest were 31·20 in Tarwadi and 30·86 in Mahim; the lowest were in the business locality of Fort South (8·95) and in Market section (9·81). The general death-rate was 70·04, compared with 59·61 in the previous year, and 36·08 for the decennium 1909-18; but after applying corrections for new arrivals not belonging to Bombay, and inmates of war hospitals, the mortality, as based on the available data, works out to 67·22 per 1000, representing 65,847 deaths. This ratio needs further correction for deaths of Bombay inhabitants occurring "up country"; but these may be held to be balanced by the deaths of visitors and persons passing through the city, as the chief port of arrival and embarkation in India. The infant mortality was 499·15 per 1000 live births, compared with 434·8 and 304·2 in 1918 and 1917 respectively: the chief causes of death were diseases of the respiratory and nervous systems and debility, which, combined, accounted for 10,143 out of the total 13,534 infantile deaths. Among Hindus the ratio was 737·92, among Mussulmans 562·36; while for Europeans it was 230·76, and for Parsees only 224·56. The highest infant mortality (891·8 per 1000 births) occurred in Market section, and the lowest in Walkeshwar (307·6). An instructive diagram shows that the infant mortality among families living in single-room tenements was 83·1 per cent. of the births registered; in those living in two rooms it was 56·5, in three rooms 35·8, in four rooms 18·9, and in hospitals only 11·1 per cent. Unfortunately 79·9 per cent. of the population live in single-room tenements. The work of the Bombay Sanitary Association, according to the scheme inaugurated by Lady Willingdon in 1914, has been continued and extended. Maternity homes, infant milk depôts and infant welfare centres are in operation, under a ladies' committee, with Her Excellency Lady Lloyd at their head.

Incidence of Disease amongst the General Population.

In regard to the general population the largest number of deaths was, as usual, recorded under respiratory diseases, amounting to 24·55 per 1000, as compared with 23·97 in 1918, and 10·51 in the preceding decennium (1909–18). Next to this group cholera was the most fatal, with 8455 deaths, or 8·63 per 1000, compared with 1·69 in 1918 and 0·50 in the decennium. It became epidemic in the middle of December, 1918, and was gradually declining in January, but unfortunately, owing to the labour strike, "which began on 9th January and was unprecedented in duration as well as in magnitude, the incidence of the disease attained appalling proportions," reaching its height in the week ending 1st February. After this it began to subside. Of the 9658 attacks and 8455 deaths from cholera in 1919, 9304 attacks and 8206 deaths occurred during January and February. The type of the disease was evidently most severe; the case-mortality, or fatality, was 87·5 per cent., and for the two months, January and February, when the epidemic was at its height, 88·2 per cent. Deaths occurred in every registration section throughout the city, those most severely affected being Parel (22·27 deaths per 1000) and Sewri (20·29). Vigorous measures were taken, the medical, conservancy, and disinfecting staffs strengthened, and inoculation was offered free to all. Owing to this energetic action of the medical and municipal authorities the epidemic was practically brought to an end in February, although cases occurred sporadically throughout the rest of the year. There were 826 cases of plague, with 702 deaths (0·71 per 1000), this being the 24th year of its continuous presence in Bombay. Influenza was prevalent, especially in May and June, but the mortality (1·98) was much less than that of 1918, which had been 4·04 per 1000. The deaths registered as due to tuberculosis (2780, or 2·83 per 1000) were in a higher ratio than in the preceding quinquennium (2·06), but it is pointed out that this does not necessarily signify a corresponding increase in the incidence of the disease, as owing to modern methods of diagnosis many cases, formerly returned as fevers and bronchitis, are now correctly shown as tuberculosis. It was most prevalent in Upper Colaba (9·63 deaths per 1000) and Sion (8·93) sections; in Mazagaon the ratio was only 0·29. For Hindus the ratio was 2·62, for Mussulmans 4·13, and for Europeans 0·84. The King George V. Anti-tuberculosis League carries out a good work in close coöperation with the Health Department; 1003 patients attended the two dispensaries which the League maintains, and patients too ill to attend are visited by the medical officers at their own homes. A sanatorium was opened on Bhoiwada Hill, at Parel, in April, with 20 beds, where 57 cases were cared for, greatly to the comfort of the patients, and with much value in preventing spread of infection in their homes. Ague and remittent fever caused 5071 deaths, and in addition 262 are returned under "malaria." The results of an extensive inquiry into the prevalence of enlargement of the spleen showed that, among 11,140 children examined, this condition was present in 1·37 per cent. for Bombay as a whole; in Ward G, comprising Mahim and Worli sections in the north of the island, among 5106 examined not a single case of enlarged spleen was detected; on the other hand, in Dhobi Talao section (Ward C) 4·22 per cent., in Fort North, 4·56 per cent. and in Esplanade section 5·65 per cent. of the children examined were found to have enlargement. In 1918 these last two sections had shown spleen rates of 4·73 and 2·96 per cent. respectively; in 1909 the ratios had been 49·44 and 73·88. The water reservoirs on Malabar Hill have been protected with reinforced concrete, and all filters abolished; many ponds and tanks have been filled in, and many wells either filled in or effectually protected. Almost all the cisterns in the city have been made mosquito-proof.

Dr. Sandilands draws attention to the need of hospital accommodation for tuberculous patients, and for extending the existing provision for the treatment of infectious diseases; he considers that a total accommodation of 1000 beds is required. The condition as regards vaccination in Bombay cannot be considered as satisfactory. The number of children vaccinated, under one year of age, was 12,064; it has been already stated that there were probably 27,114 births during the year. The deaths from small-pox under one year of age numbered 198; 161 of these cases had not been vaccinated; in the remaining 37 the condition as regards vaccination was unknown. On the other hand, out of 9218 pilgrims leaving for Mecca 97·54 per cent. were vaccinated in Bombay before embarkation. This exhaustive report is fully illustrated with diagrams and tables. A plan of the city would have increased its interest, and this addition we suggest should be made in subsequent issues.

MEDICINE AND THE PUBLIC.

To the Editor of THE LANCET.

SIR,—Modern medical progress means a recognition of the fact that disease in the individual affects in greater or less degree the whole community. From this it follows that the whole community ought to be interested in medical science. Evidence of the growth of public interest in this direction is shown by the amount of space which the daily press devotes, sometimes well and sometimes not so well, to medical questions of the day, but if the revelation of medical science is to keep pace with its progress there is needed a strong movement to interest and educate the constituency. Has all been done that might be done? During the war the Royal College of Surgeons of England did excellent work by organising lectures and demonstrations for ambulance workers and V.A.D.'s, and there does not seem to be any reason why its facilities as well as its authority should not be used to broaden public knowledge of matters which concern the national health. There are many directions in which this idea could be developed, with valuable results. I am, Sir, yours faithfully,

April 4th, 1921. WILLING TO LEARN.

A GERMAN MANIFESTO ON VITAMINS.

A RECENT issue of the Official German Health Publications contained the following manifesto on accessory food substances:—

"The coming months threaten us with grave food difficulties, similar to those of the winter and spring of 1917. Lengthy research has established the fact that the ill consequences of insufficient diet depend not only on the lack of total quantity, but, in much higher degree than was once thought, on the lack of certain accessory substances (vitamins), essential alike in adults and children to the well-being of the body, but distributed very unevenly in the usual food-stuffs. Added in sufficient amount these substances can to a certain extent compensate for insufficient total quantity of food. Conversely, in their absence, even the most abundant diet is not able to ward off English disease (rickets), bone softening, watery swellings (œdema), nutritional changes in the blood and the nerves, loss of resistance to tubercle and other diseases. Unfortunately, a great part of the food-stuffs which contain in high degree these important accessory substances—e.g., fresh milk, best dried milk, butter, whole-milk cheese, cream, fresh meat, liver, kidneys, heart, brain of animals, fat fish, eggs, dripping, and lard—are hard to obtain and very costly. Their lack can, however, be made good also by cheaper material.

Emphasis should therefore be laid on such food-stuffs, of which the most important are: *Animal*—cod-liver oil. *Grain*—wheat (wholemeal, including the bran as in Graham bread); the germ of corn, specially of wheat, as in the preparation "materna"; germinating grain, as in the production of malt. *Pulses*—peas, beans, lentils, soya beans (also in dry form). *Greens*—all forms of fresh green leaves, all kinds of cabbage and spinach, provided that they are only steamed and not brought to the boil. According to recent research, the stinging nettle provides a tasty dish rich in vitamin. Any kind of salad, varieties of lettuce at the head; further, carrots (also expressed carrot-juice for children). *Fruits*—nuts, dessert fruit, lemons and lemon-juice. As vitamin-rich fruit are apples specially to be noted; oranges are rich in vitamin, but are at present costly. *Various*—fresh yeast and its preparations; malt extract in certain forms has been found to contain vitamin. The substances in question pass from the expectant mother to the fœtus, and from the nursing mother into her milk. When these substances are lacking the body of mother and child suffers even with abundant food. For detailed information ask your doctor!"

The signatories to the manifesto are Professors V. Bergmann, Ellinger, Embden, v. Noorden, Quincke, and Strasburger, members of the faculty of medicine at Frankfort University, and Hr. Schlosser, president of the City Health Department.

A PROGRAMME OF DIET.

A MEDICAL practitioner forwards to THE LANCET a rather quaintly worded advertisement in the form of a typewritten letter that he has received, possibly in common with many of his colleagues. It professes to come from a person who has suffered severely from asthma, but who "by following out a carefully thought out Programme of Diet," has cured himself. "It is very easy to follow, being straightforward and concise (if typed about a page and a half), and no more expensive than ordinary fare, being really a guide to asthmatics what to avoid than recommending special foods, and in no way interferes with business." The advertiser is too modest to fix a fee, or is afraid that his modesty might underestimate the gratitude of his possible correspondents, and so operate to his detriment. He offers to send his rules of diet "on receipt of your cheque or Treasury notes for what you consider would be fair for above information." It leaves one wondering how many Treasury notes the sender expects to extract from the medical profession by such simple means.

COMMERCIAL VACCINES.

Messrs. Parke, Davis and Co. have issued a tenth edition of the pamphlet on vaccine therapy, which contains instructions for using the bacterial vaccines prepared in the vaccine laboratory of the Department of Therapeutic Inoculation at St. Mary's Hospital, London. The sections of this pamphlet relating to acne, streptococcal infections, influenza, typhoid fever, and whooping-cough have been largely rewritten. New vaccines have been added as follows: Diphtheria bacillus vaccine for the treatment of "carriers" and convalescents, Anti-rheumatic vaccine, Anti-plague vaccine, several Anti-influenza vaccines and Mixed gonorrhœa vaccine. The composition of the following vaccines has been altered: Acne and Mixed acne, Antisepsis and Whooping-cough. The Mixed vaccine for colds, the Anti-catarrh vaccine, and the Mixed anti-influenza vaccine (St. Mary's Hospital formula) are now issued in sets of three graduated doses for the prevention and treatment of coryza and influenza. The stock vaccines are the same as those used in the Inoculation Department, St. Mary's Hospital, and have been standardised by observation of their effects on patients. A proportion of the proceeds of the sale of these vaccines goes to the upkeep of the in- and out-patient departments, and the laboratories of the Institute of Pathology and Research at St. Mary's Hospital.

Messrs. Allen and Hanburys, Ltd., in their "Medicamenta Recentia" present in concise form details of the materia medica of their manufacture. The method of arrangement is alphabetical, and a therapeutic index with cross references makes for convenient use. There is a very complete list of vaccines and kindred preparations, many of them deriving from the Lister Institute, with suggestions as to dosage and method of administration. The series includes Acne bacillus vaccine, Bacillus septus (Hofmann) vaccine, Calf vaccine lymph, Cholera vaccine (multivalent), Coley's fluid (new) for cancer, Colon bacillus vaccine, Compound catarrhal vaccine, Compound influenza vaccine, Dental streptococcus vaccine, Gonococcus vaccine, Micrococcus catarrhalis vaccine, Paratyphoid vaccine, Plague prophylactic, Pneumobacillus (Friedländer) vaccine, Pneumococcus vaccine (multivalent), Pollen toxin vaccine, Staphylococcus vaccines, Streptococcus rheumaticus vaccine, Typhoid vaccine, Typhoid and paratyphoid vaccine, Typhoid, paratyphoid, and cholera vaccine, Whooping-cough vaccine, and various Tuberculins for diagnostic and curative use. Prices are not given.

WILLOCINE: A FRUIT-ACID TOOTH-PASTE AND TOOTH-POWDER.

Dr. W. J. Henson, who calls our attention to this fruit-acid tooth-paste and tooth-powder, accounts for the prevalence of pyorrhœa and dental caries by the use of alkaline dentifrices which retard the natural flow of saliva. Willocine combines a colourless salt prepared from willow charcoal (THE LANCET, 1917, ii., 53) with citric and benzoic acids and such soluble antiseptics as menthol and thymol. Potassium bitartrate and acid phosphate of calcium take the place of chalk as a base. Willocine can be obtained from Messrs. W. E. Lowe and Co., Ltd., 8, Stafford-street, Old Bond-street, London, W.

EMIGRATION FOR THE HARD HIT.

THE Department of Colonisation and Development of the Canadian Pacific Railway have recently issued a small brochure briefly setting forth the need for migration within the Empire—both to relieve the pressure of over-population in England and to develop the resources of the great Dominions—together with information as to specific opportunities offered by Canada to a new class of emigrants, such as the younger members of formerly well-to-do families whose economic position has been rendered difficult by the war and its consequences. This new class may be subdivided into: (1) those desirous of making new homes under conditions similar to those in the old country—i.e., settlement in or near a town; (2) those who wish to acquire land near to available markets, where market-gardening or poultry-farming may be profitably carried on, or who wish to follow their old profession or business in a new country; and (3) those anxious to settle on the land with experience already gained in England or under guidance by Canadian experts, as individual or group ranchers. Such emigrants have generally sufficient means to pay for their passages and to make a start in their adopted country; and there is room for all of them, no less than for the farmers, agricultural labourers, and domestic servants who are in constant demand. The recently formed "Western Canada Colonisation Association," the aims of which are described as "largely altruistic," proposes to establish a welfare section to assist settlers taking up land under its auspices—and, presumably, also to help anyone wishing to settle in or near a town for residential or business purposes.

A few localities are instanced, short descriptions of them being given at the end of the brochure. Of the Columbia-Kootenay Valley, between the Rocky Mountains and the Selkirks and south of the Railway Belt, we read as follows:—

"The climate is healthful and enjoyable at all seasons, although the temperature shows a wide variation. Blizzards and cyclones are unknown, and bright, sunny weather, winter and summer, is the rule. The summers are dry, with occasional hot days, the mean temperature being about 60° and the maximum about 95° F. The heat, being dry, is not oppressive and the nights are always cool. From May 1st until the end of September the general climatic conditions are delightful. The winters are long and subject to the Chinook winds, which temper the cold, but there is a great deal of sunshine during the winter months, and when the temperature is low there is little wind. Sleighing usually lasts from two to three months. ...... The conditions are particularly well adapted for horses, cattle, and sheep. The large, open ranges provide an abundance of summer grazing, and the cultivated portions provide good hay for winter feeding. Dairy cattle give good returns, and the climatic conditions are also very favourable to the production of honey and the rearing of poultry and turkeys. Alfalfa and clover grasses, peas, and potatoes are some of the most successful crops grown in the valley. Cereals of all kinds produce heavy yields. Peas do exceptionally well and are free from the attacks of weevil; the growing of peas for seed should prove a profitable undertaking. Potatoes cannot be surpassed in yield or texture; other hardy vegetables do remarkably well, as do tomatoes and bush fruits."

Similar short descriptions, including notes on timber, irrigation, and railway transport, are given of the Columbia Valley and of the Elko Lands, East Kootenay. Those who feel attracted by the opportunities offered by the Dominion are invited to ask for general and detailed information from the C.P.R. Department of Colonisation and Development, 62-65, Charing Cross, London, S.W.1, or from any of the agents of the Company in the United Kingdom.

Oliver-Sharpey Lectures

ON THE

NATURE OF FLUTTER AND FIBRILLATION OF THE AURICLE.

Delivered before the Royal College of Physicians of London on April 12th, 1921,

BY THOMAS LEWIS, M.D., F.R.C.P. LOND., F.R.S.,

PHYSICIAN TO THE STAFF OF THE MEDICAL RESEARCH COUNCIL; PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL, LONDON; HONORARY CONSULTING PHYSICIAN TO THE MINISTRY OF PENSIONS.

LECTURE I.—AURICULAR FLUTTER.

[AFTER some introductory remarks, in which he mentioned as his co-workers Dr. Thomas Cotton and Dr. A. N. Drury, of this country; Dr. H. S. Feil, Dr. W. D. Stroud, and Dr. H. A. Bulger, of the United States; and Dr. C. C. Iliescu, of Bucharest, Dr. Lewis proceeded:—]

SOME NORMAL FEATURES OF THE CONTRACTION PROCESS.

Let me first briefly describe the relevant events when normal heart muscle contracts in response to a natural or artificial stimulus. The first event of which we possess knowledge is that it passes into what is termed the *state of excitation.* By this we mean that the muscle develops a charge, just as a battery develops a charge, and that currents flow through it and the surrounding tissues. The charge is such that the active muscle becomes relatively negative to that which is still inactive, in the sense that the zinc terminal of a copper-zinc battery is negative to the copper. These electrical changes, associated with muscular activity, are of sufficient magnitude to be recorded by means of sensitive instruments, and they yield the pictures now spoken of as electrocardiograms. The electrical change in the muscle is the immediate precursor of contraction[1]; first the muscle becomes excited (or charged), secondly it contracts. The two events are separated in the mammalian auricle by a small time interval of three-hundredths of a second or less.

Now the process of excitation is not simultaneous in all parts of the muscle; it begins at the point first stimulated and spreads from this point. Stimulate a point in the centre of a sheet of muscle and the wave spreads concentrically, as does the ripple on the surface of a pond into which a pebble is thrown. It is conducted from one muscle element to the next as a wave, which is termed the *wave of excitation.* Similarly with the contraction process itself; this also spreads as a wave which accurately follows the course travelled by the wave of excitation. It may be likened to the second ripple on the pond. For our present purposes and to simplify the conception we may regard these waves as one, signalling itself as it proceeds, first electrically (first ripple), then mechanically (second ripple). When, therefore, I speak of the wave of excitation in the auricle and of the course it takes, you may picture in your minds the wave of contraction without fear of serious misconception. Nevertheless, I should, perhaps, be guilty of inaccuracy if I spoke of the wave of contraction, because our studies have been mainly, though not exclusively, directed to the wave of excitation; for movements of the latter are to be recorded with far greater accuracy than movements of the former.

Movement of the excitation wave is recorded by connecting a sensitive galvanometer directly to the surface of the muscle. As the wave passes the chosen point the galvanometer yields a sharp deflection, and this may be photographed and accurately timed against the events in some other region of the muscle. I do not propose in the present lectures to enter upon a detailed description of this delicate method, but am content to declare that we can time the arrival of this excitation wave at any point of the muscle surface with such accuracy that the error is no more, and usually less, than one-thousandth of a second; that by using two or more recording instruments simultaneously we can trace out the paths taken by waves of excitation as they travel through the muscle; and that we can estimate very accurately the time lost in the passage from point to point in different circumstances.

The wave of excitation, the first of the contraction process, travels until it involves the whole surface of the muscle; it travels in every available direction until it has exhausted all tracts of responsive muscle. Starting in the centre, it travels until it comes to the boundaries; there it ends, for at the boundary it finds no further tracts of responsive muscle through which to pass. Appropriately you may liken the spread of the excitation wave to the flame of a prairie fire. It spreads concentrically wherever it finds inflammable material; it cannot return over its scorched wake, neither can it proceed when it reaches the bounds of the dried acres. The wave of excitation leaves the muscle over which it passes in a non-inflammable, or, as it is termed, *refractory state,* and that muscle is incapable of carrying a second wave of excitation until its original inflammable state is restored. The period during which this restoration is effected is called the *refractory period* of the muscle; in the natural beating auricle of the dog it lasts from a fifth to a tenth of a second; its duration is approximately the same as the duration of the contracted state of the muscle.

From these preliminary observations I pass to what may be termed the "ring experiment."

THE RING EXPERIMENT.

The ring experiment was first performed by Mayer in 1908; he used the contractile bell of the jelly-fish and subsequently he utilised rings of muscle cut from the ventricles of turtles. His experiments were repeated and amplified by Mines in 1913 upon rings of muscle cut from the auricles of teleostean fishes. In 1914 both Mines and Garrey reported that they had obtained similar effects in rings of muscle cut from the dog's ventricle.

The experiment from our present standpoint is fundamental; I shall describe it therefore in some detail.

Suppose that we stimulate a ring of muscle, such as is depicted in Fig. 1, at *a*, the centre point of its lowest quadrant, and start in it by means of a single shock a *wave of excitation.* This wave, as soon as it has involved the whole cross section of the ring, develops two crests, which travel rapidly along the two limbs of the circle until, as shown in the serial diagrams (Fig 1, *1–4*), they meet at point *b*, the centre point of the highest quadrant. At the instant the crests meet the whole ring has become involved by the wave; the whole has passed into a state of excitation; it has all become "refractory." When, therefore, the two crests meet at point *b* movement is brought to an end; like two waves of flame, two waves of excitation meeting do not over-ride, each crest forms an impassable barrier to the other. The ring of muscle remains in this state of excitation for a period and then recovers. It recovers in the order in which it has become involved, it begins to be "responsive" in its lowest quadrant (at *a*) first of all. The wave of "responsiveness" travels similarly as two crests along the two limbs of the ring (Fig. 1, *5–8*) until they also meet and coalesce at *b*, the centre of the highest quadrant. The ring of muscle has now returned to its original condition; it is once again wholly in the responsive state.

Such is the series of events when the muscle of the ring responds to a single stimulus. If the ring is stimulated by means of slow rhythmic shocks each shock awakens a like series of events, providing that the intervals between the shocks are amply sufficient to permit recovery. Each stimulus yields a double-crested wave of response, which ultimately involves the whole ring. It will be evident that if in rhythmic stimulation the second shock falls upon the ring while it is in the

---

[1] That the electrical change precedes the contraction is at the moment the accepted view, though the interval is acknowledged to be very short.

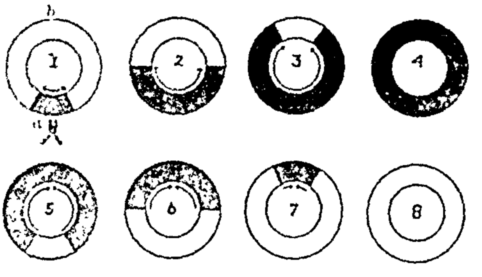

FIG. 1.—A diagram illustrating the progress of a single wave passing through a ring of muscle as a result of stimulating it at *a*. The black portion of the ring represents the refractory state, and the figure shows its progress through the ring till it involves the whole (*4*); later the figure shows its subsidence.

condition represented by Fig. 1, *6*, a fresh wave may be propagated at *a* before the response to the first shock has subsided at *b*. In such circumstances two waves will be moving through the ring at one time, as depicted in Fig. 2, *6–8*.

We come now to a different form of reaction; it is that which especially concerns us. It happens when the rate of rhythmic stimulation is raised to a critical point—namely, when the intervals between the shocks are such that each falls on the muscle at a time when responsiveness in this muscle has not wholly recovered. In such circumstances the wave propagated by stimulation may be unable to travel with its usual freedom in all directions. From time to time it is found that a wave propagated from the point of stimulation can pass in one direction only. It starts well enough, perhaps, and reaches two points of the ring A and B (Fig. 3); but at *A* it finds the muscle still insufficiently responsive, while at B recovery is more advanced. At A progress comes to an end, while at B the crest continues to move. Suppose that at this instant stimuli are withdrawn; the conditions are peculiar. Instead of two crests advancing to meet and interfere, there is now but one, and it is free to circulate, for as it comes to each new segment (C, D, E) of the ring it finds this segment excitable (Fig. 3, *2* to *4*). The single-crested wave consequently progresses around the whole ring, and, coming back to its starting-point, finds that this muscle also has recovered (Fig. 3, *5*); it proceeds so long as the conditions remain unaltered; it continues its course as a circulating wave which has no ending (Fig. 3, *6* to *10*). Thus it has been shown that, the conditions being nicely controlled, the last stimulus of a series may originate, not a single response of the ring, but an unlimited series of responses. Mines saw the wave continue to circulate for minutes, Mayer saw it continue for very many hours; this is what is meant by circus movement; it is constituted by a wave of response, which travels continuously along a re-entrant path of muscle.

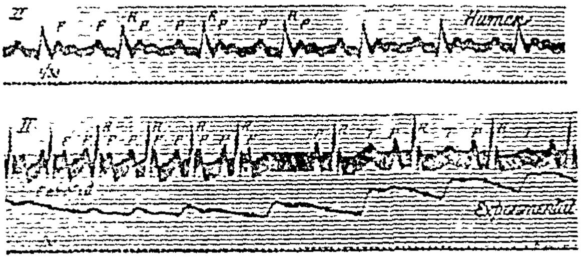

FIG. 4.—Examples of auricular flutter, clinical and experimental. The upper or clinical curve was taken from a patient in whom flutter was continuous. The auricle (*P*) is beating at a rate of 228 per minute and regularly; the ventricle (*R*) at half that rate. The ventricle responds to alternate beats of the auricle; the beat of the auricle to which there is no response falls with the beat of the ventricle. The lower or experimental curve shows the end of a period of flutter and the return of the normal rhythm. The *first half* of this curve is to be compared with the upper curve. During the period of flutter the auricle (*P*) is beating rapidly and regularly; the ventricle (*R*) at half the rate. The ventricle responds to alternate beats of the auricle; the beat of the auricle to which there is no response falls with the beat of the ventricle.

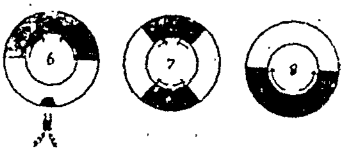

FIG. 2.—A second stimulus enters the ring while it is in the condition shown in Fig. 1, *6*. While the first wave is subsiding the second wave spreads.

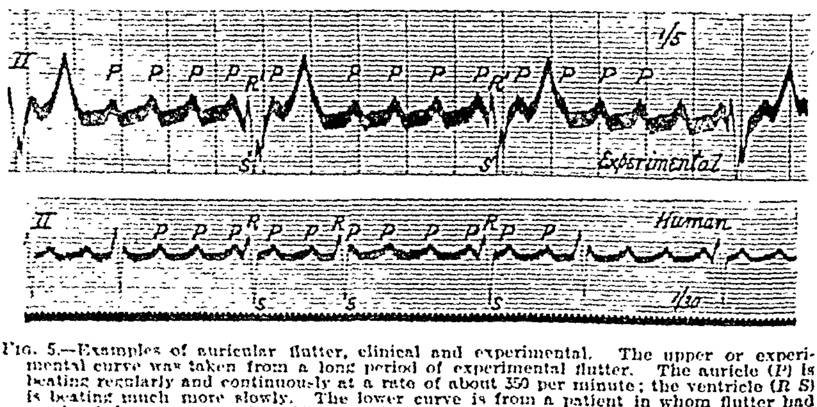

FIG. 5.—Examples of auricular flutter, clinical and experimental. The upper or experimental curve was taken from a long period of experimental flutter. The auricle (*P*) is beating regularly and continuously at a rate of about 350 per minute; the ventricle (*R S*) is beating much more slowly. The lower curve is from a patient in whom flutter had persisted for many months. The auricle (*P*) is beating regularly and continuously at a rate of about 270 per minute; the ventricle (*R S*) is beating much more slowly.

AURICULAR FLUTTER.

We may now examine a condition of the mammalian auricle, to-day called auricular flutter. Flutter, as we now understand it, was first clearly described in a patient by Hertz and Goodhart in 1909; they studied their case by means of venous curves, showing the auricle to be beating continuously and regularly at a rate of 234 per minute. Their description was quickly followed by the more ample records of Jolly and Ritchie, and of other writers. The rate of the auricular beating in flutter is from 230 to 350 per minute; the action of this chamber is remarkable, not only for its high rate, but for its regularity. It is to be recognised with the greatest certainty in electrocardiograms, of which examples are shown in Figs. 4 and 5. The condition is also remarkable because it continues uninterruptedly for long periods of time. Sometimes it may occur in short paroxysms, more usually it comes to stay for months or years. Its nature until quite recently has remained altogether mysterious, though very numerous observations have indicated its close affinity to the condition called fibrillation. Thus flutter is often converted into fibrillation by the administration of digitalis. There have been few satisfactory records of a similar experi-

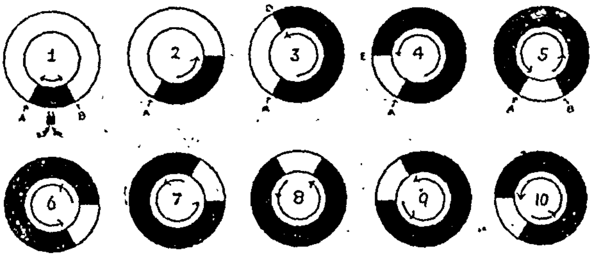

FIG. 3.—A diagram to illustrate the establishment of a circus movement in a ring of muscle. The ring is stimulated in its lower quadrant and the wave spreads to A and to B. At A it is blocked, but from B it continues around the ring. When it arrives at E (*4*) the refractory state at A is passing, and so the wave continues to travel around the circle (*5–10*).

mental condition. The term "flutter" was used by McWilliam as early as 1887; that was in the days when the two conditions, flutter and fibrillation, were not definitely distinguished. The first electrocardiograms of experimental flutter—and these curves are alone really distinctive—have been obtained during the past few years. We are now certain that a condition identical with that found clinically may be produced experimentally in the dog's auricle; this we have been taught by clinical and experimental electrocardiography.

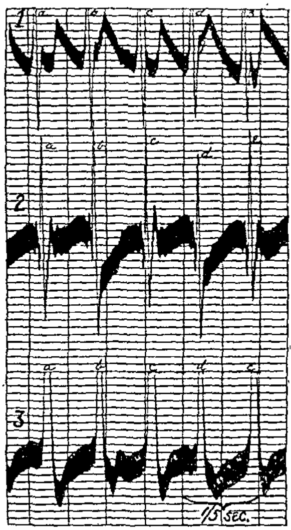

FIG. 6.—Three electrograms recorded simultaneously from the tænia terminalis of a dog while the auricle was fluttering. The top curve (1) was taken from the inferior caval, the bottom curve (3) from the superior caval, and the centre curve (2) from the mid region of the tænia. The record corresponds to five cycles of flutter (*a–e*). As each excitation wave passes, it signals itself by means of a sharp upward movement of three recorders. Recorder *1* moves first, recorder *2* a fraction of a second later, and recorder *3* a fraction of a second later still. The order of excitation is 1, 2, and 3; the wave is passing up the tænia.

In investigating disease there is one well-known and most fruitful method of approach—it is to produce in animals a condition identical with that seen in the patient. When this has been accomplished it becomes possible to inquire into the precise nature of the disturbance. If and when that knowledge is obtained we are in a position to consider rational plans of treatment. As I have related, in the case of flutter of the auricle, the first step has been taken. A continuous and rapid action of the dog's auricle can be produced in several ways, notably by rhythmically stimulating the organ with induction shocks at a rate of 300 to 600 per minute. The auricle is driven rhythmically and rapidly for a few seconds, and the stimuli are then abruptly withdrawn. In a certain proportion of such experiments a rapid action of the auricle continues after stimulation has ceased. The rate of action is not usually that of the rhythmic shocks which provoked it; it is usually less. For the moment our chief concern is not the method of producing this rapid and continuous action, but its nature. Its nature is variable, but amongst the after-effects of stimulation a condition identical with clinical flutter is seen from time to time. It is not every auricle which is predisposed to flutter; it is not every stimulation which will invoke flutter in the predisposed organ. That, however, is immaterial, providing that we can produce it, and can be certain when it is produced that it is identical with the clinical condition. The electrical curves, clinical and experimental (Figs. 4 and 5), leave us with no doubt on this subject; these curves, so delicately analytical, place the conclusion beyond question.

Experimental flutter having been produced, its nature is investigated by mapping out the path taken by the excitation wave while flutter is in progress. A single illustration of method will perhaps suffice. The auricle of a dog has been forced into a state of flutter, as ascertained by electrocardiograms taken by methods comparable to those used clinically. The flutter continues uninterruptedly. Three points are now chosen in the line of the tænia terminalis, and to each of these a sensitive galvanometric recorder is connected. The curves of these recorders write simultaneously. (Fig. 6.) As the excitation waves flow through the muscle they pass beneath the several contact points, and at each the passage is signalled. The curves, considered together, show that each wave is passing regularly up the tænia from the region of the inferior to the region of the superior cava, and we are able to measure the rate at which it is travelling. This record is published to illustrate the orderly character of the events as the cycles are repeated, and to indicate with what certainty the direction taken by the excitation may be ascertained. Actually a slightly different plan of campaign to that described is usually adopted. It consists of maintaining one lead as a standard and moving a second to various points of the auricle, timing the arrival of the excitation wave at its several parts relative to the standard lead, and finally of its arrival at the several parts relative to each other. To exemplify in a simplified fashion a complete experiment I may use Fig. 7. This figure shows the natural outline of the auricle as it is seen from above. The two appendices project upwards in the diagram; the superior and inferior venæ cavæ are represented as transsected. The figures *1*, *2*, and *4* in the lower diagram lie on the tænia terminalis. The

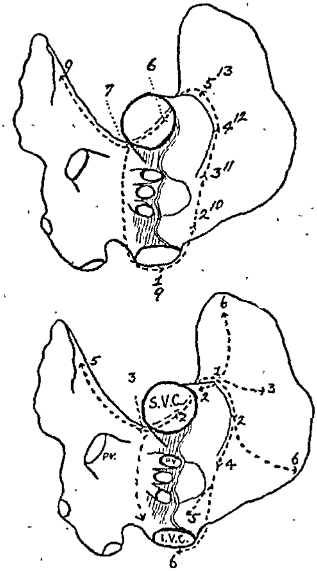

FIG. 7.—A natural outline of a dog's auricle, showing the paths of the excitation wave (broken lines) while the heart beats naturally (lower diagram) and during flutter (upper diagram). The numbers indicate the approximate order in which various parts of the musculature received the excitation wave.

order of excitation displayed by this animal while the heart beats normally is indicated in the lower diagram by the figures *1*, *2*, *3*, *4*, &c. The excitation wave, as is usual when the heart beats normally, starts in the region of *1*, the point at which the sino-auricular node or "pacemaker" lies. A little later it is to be found simultaneously at the points marked *2*. Follow the numerals and you perceive the course which it takes. It flows simultaneously along the muscular paths which radiate from the region of the node. Thus, it flows down the tænia to the inferior cava; it flows from the base to the tip of the right appendix; it flows through the intra-auricular band to the left auricle, and, still flying from its point of origin, traverses the left appendix from its base to its tip. The wave is not visible as a wave; it travels too fast for that; the whole process of spread occupies the twentieth part of a second.

In the top diagram of the figure is the essential part of the map for the same auricle in a state of rapid flutter. The order of excitation is quite different. The wave is first traced at the inferior vena cava (*1*), and it passes up the whole length of the tænia (*2*, *3*, *4*, and *5*). Reaching the top of the tænia it moves around the superior cava and flows through the intra-auricular band (*6* and *7*) to reach the left auricle. It reaches the left appendix (*9*), and at the same instant a wave is timed to emerge from the inferior vena cava (*9*). The question which at once arises is whether this second wave, emerging from the inferior cava and repeating the course (*10*, *11*, *12*, *13*, &c.) of the first wave, is a new wave, or whether it is the continuation of the old one. Is there a succession of regular waves, each arising de novo in the inferior cava, or is there a single circulating wave? This question is answered by two considerations. If we propagate a wave artificially from the inferior cava this spreads equal distances in equal times; it arrives at the two points *4* and *7* simultaneously. That is not the case in flutter; here it passes through point *4* to reach point *7*. But the *decisive argument is found in the time relation of the* wave: knowing the rate at which it travels along its path (*1*, *2*, *3*, *4*, *5*, *6*, and *7*) we can calculate how long it should take to move from *7* to *9*, and can compare this calculated time interval with the actual interval observed; these are found to be the same within an inconspicuous margin of error. There can be no doubt, then, that we are dealing with a wave which circulates. It circulates in this experiment around a natural ring of muscle formed by the orifices of the two venæ cavæ. Looked at from above, the movement is in the opposite direction to the hands of a clock. In this instance it completed one circuit in 0·16 of a second; it completed, therefore, 380 circuits in one minute, and that was the rate at which the auricle beat.

The experiment which I have described is one of several, but it will suffice to illustrate the kind of evidence we possess of circus movement in the auricle. Flutter consists essentially of a continuously circulating wave. The path which this central or re-entrant wave usually takes is the one I have described, but that is not invariable. Sometimes in flutter the course is different: thus, the flow may be clockwise over the same route. In other cases only one cava is encircled; the path is shorter, and the circuits are more quickly completed consequently. In other cases, though these are not so clearly evidenced, the circus movement is around other natural orifices, such as the mitral orifice. These variations are chiefly of consequence because they render the experimental work more difficult; the important conclusion is that the wave can be shown to circulate when the auricle flutters. The proof of circus movement in the auricle is not confined to the class of experiment which I have cited; there is much more evidence that I can now give you; taken as a whole I believe it to be quite conclusive.

Now the wave as a whole is not, of course, confined to the central or re-entrant path; as it passes along this path offshoots are sent through the appendices to their tips and into all other regions of the auricular muscle. Thus the movements of the whole auricular tissue is controlled by the circulating wave. There is the central or mother-wave, and there are its centrifugal offshoots into the remaining tissue.

Such is flutter as it occurs in the dog; such, therefore, is flutter as it occurs in man. In the dog we may see flutter last for hours; in man it may last, not for hours, but for years. I have known it to continue unceasingly for as long a period as seven years; for all we know it may continue even longer. A single wave continuously circulating for seven years: that, perhaps, may seem to be a remarkable conclusion; nevertheless, it is one we are now bound to accept.

THE FACTORS CONTROLLING FLUTTER.

A condition comparable to clinical flutter may, then, be produced in experiment; we have seen that when this experimental flutter is investigated it proves to consist essentially of a circulating wave. We may next consider the precise factors which maintain this circus movement. Refer back to the diagrams of the ring experiment and it will be clear that three factors are involved. They are:—

1. The length of the central path.
2. The rate at which the wave travels.
3. The duration of the effective refractory period.

It must be evident that if the wave is to continue circulating a gap must exist between the crest of its advance and the wake of its retreat. As the crest travels it must always find the muscle which it enters in the responsive state. If for any reason the gap becomes closed the wave will proceed no longer and the rapid action of the auricle will cease. The three factors named, and these alone, control the length of the gap. The duration of the refractory period at any given point must always be less than the time spent by the travelling wave in completing its circuit; this circulation time depends on the length of the path and the rate of travel. Now the rate of travel from point to point in the dog's auricle beating normally is approximately 1000 mm. per second, and the length of the refractory period at normal heart-rates is approximately 0·15 to 0·2 of a second. In 0·15 to 0·2 of a second the wave will travel through 150 to 200 mm. of muscle. On the basis of these values a circus movement could not establish itself in a ring of muscle of less than 150 to 200 mm. circumference. But it is known that much smaller circuits than these become established. What is the reason? The reason is that when the auricle flutters the refractory period is reduced; also, the rate of travel is usually reduced. These reductions both occur in response to an increased rate of beating such as prevails in flutter. Both changes facilitate the establishment of relatively short circus movements. The precise relations of the three controlling factors have now received close investigation. They are variable in different circumstances, but may be illustrated by a type experiment. A dog's auricle is fluttering at a rate of 500 per minute. Each circuit is completed in 0·12 of a second. The circuit has a length of 60 mm. The rate of travel is not 1000 mm. per second but 500 mm. per second. The rate of travel is but one-half the natural rate; that is so because the rate of beating is so high that the muscle is hard put to it to conduct the impulses. The length of the effective refractory period is not 0·20 but 0·10 of a second; it has become reduced with the rise of heart-rate. The cycle is divided into two parts—a refractory phase of a tenth of a second, a responsive phase of a fiftieth of a second. The crest of the wave is constantly but a fiftieth of a second behind its own wake; it travels behind it at a distance of only 10 mm. We have direct and conclusive evidence that these figures may be taken as usually representative of the gap which exists; it is a minute gap, yet upon its existence the continued progress of the wave absolutely depends. To the question of this all-important gap I shall return at a later stage; it is a gap which will command the attention of many workers in the near future, for upon our power to influence its length our success in treating flutter and, as we shall see, the closely allied condition fibrillation, will very largely depend. If by any means we could close that gap we could bring flutter to an abrupt termination.

A Hunterian Lecture

ON THE

GENERAL INDICATIONS FOR OPERATIVE EXPLORATION IN NERVE INJURIES.*

Delivered before the Royal College of Surgeons of England on Feb. 9th, 1921,

BY HARRY PLATT, M.S. LOND., F.R.C.S. ENG.,

SURGEON-IN-CHARGE, ORTHOPÆDIC SERVICE, ANCOATS HOSPITAL, MANCHESTER; SURGEON-IN-CHIEF, GRANGETHORPE ORTHOPÆDIC HOSPITAL (MINISTRY OF PENSIONS), MANCHESTER.

IT has been found impossible to enunciate any hard-and-fast rules in connexion with the *indications for* the operative exploration of an injured nerve trunk. In actual experience the patient does not come under the observation of one surgeon from the time of the infliction of the injury to the period at which the necessity for a reconstructive operation arises. But certain broad principles are to be followed in arriving at a decision on this point. It is assumed that before any exploratory operation is undertaken the condition of the limb as regards general nutrition shall have reached the optimum stage, and that after the occurrence of sound healing of the wounds every effort has been made to loosen cicatrices in the skin and deeper parts and to obtain the mobilisation of stiffened joints. The operation performed under the conditions of massive scarring will in any case be difficult, and may even be unsuccessful in effecting repair of the nerve. The chances of prospective failure must dominate the immediate outlook of the surgeon.

We may state that an exploratory operation is either justified, or is inevitably needed, under the following conditions:—

1. Where the syndrome of complete interruption has persisted unchanged after a period of observation during which repeated clinical examinations have been carried out. In the choice of the limits of this period of delay we are influenced by the known time after the injury or suture at which the signs of recovery should be expected. The early sensory changes—viz., recession of the area of protopathic loss, or the clinical evidence of the neurotisation of muscles supplied by the proximal branches—are seen at the earliest at or about the fourth month. As a working plan a period of observation lasting six months is reasonable, although it must be admitted it is essentially an arbitrary one. Recognising that the anatomical limits of the lesion are sometimes definable in a given case before operative exploration, this full period of delay is often unnecessary, and, in fact, inadvisable, providing that the condition of the limb is such as to render any operation feasible. With regard to the stage of safety, after complete healing of the wound a period of four to six weeks should be taken as a minimum, but may be prolonged according to the influence of local conditions. In a considerable number of cases the attainment of sound healing, and the preliminary nutritive treatment, occupy the full six months' period of probation.

2. Where the syndrome of incomplete interruption has continued without change for six months and particularly when this is represented by the distal syndrome.

3. In the presence of the syndrome of irritation, either of a moderate degree showing no signs of subsidence, or in the severe type—causalgia—at the earliest possible moment.

THE PRINCIPLES OF OPERATIVE TECHNIQUE.

I. *Preparations for the Operation.*

Before the actual operative exploration of the injured limb is undertaken, in anticipation of the probable discovery of an extensive lesion which will necessitate the wide mobilisation of the nerve trunk, every precaution must be taken to obviate or minimise the inevitable difficulty of achieving repair. Chief amongst the important preliminary steps are the provision of a wide area of prepared skin—as a routine the whole of the limb—a trial of the appropriate position of the patient and limb on the operation table, and the assembly of suitable splints or other forms of fixation apparatus which have been accurately fitted to the limb in the posture which will be reproduced at the end of the operation. Upon such careful planning depends often the ultimate success of the operation, and particularly the comfort of the surgeon during its performance, for many of the operations of suture for extensive nerve injuries are, as regards difficulty and tediousness, without parallel in the whole realm of operative surgery.

During the course of the operation the position of the limb will often be changed in order to facilitate the final steps of the actual suture. The resulting position is usually one which increases the difficulties of the closing steps of the operation, and it is essential that such a change should be carried out with as little disturbance as possible. In dealing with the individual nerves these points will be further elaborated.

II. *The Exploration Technique Proper.*

(*a*) *Exposure of the nerve trunk.*—In general most peripheral nerves are exposed in a convenient intermuscular interval, and as an invariable rule the nerve trunk is to be exposed first well above and then below the area of the actual lesion. Before the lesion proper has been rendered accessible, the physical appearance of the nerve trunk is to be noted and recorded, and particularly the changes, if any, seen at the proximal and distal limits of the region of the injury.

Next the physiological activity of the nerve trunk and motor branches, if seen, and of the muscles exposed in the operation field, are to be investigated by direct stimulation with the faradic current.

(*b*) *Importance and significance of direct electrical testing.*—It should be more universally realised that in a truly efficient technique direct electrical stimulation of the nerve trunk is an essential feature. By this method information is afforded which cannot be obtained as easily or as exactly by any other form of examination. Experience has shown that the bipolar mode of stimulation is superior to the unipolar method. Using a bipolar electrode with fine points closely approximated, any tendency to diffusion is minimised and an accurate localisation of the stimulus can be obtained.

A minimum strength of current should be used as a routine so that a rough quantitative standard can be established. One of the most obvious practical advantages of direct electrical stimulation is seen in the ease with which nerve trunks are recognised in such regions as the upper arm or axilla, especially when ordinary anatomical landmarks are lost in the scarred and destroyed tissues. Further, motor branches arising from the nerve trunk above the area of the lesion are identified at once and their physiological integrity confirmed.

Information is also provided as to the quality or absence of excitability in the muscle bellies in the operation field; but the direct use of faradic stimulation is seen in the investigation of the presence or absence of conductivity in the nerve trunk itself. A response elicited from the nerve indicates the presence of a continuity of motor axis cylinders from spinal centres to peripheral end organs, except during the period immediately following the infliction of the injury. It has been shown by Perthes,[1] in experiments on divided nerves in dogs, that the distal part of the nerve loses its capacity for faradic response in about 72 hours after section, and that during the course of the subsequent regeneration the return of faradic excitability is coincident with the appearance of voluntary power; also that for a time newly regenerated fibres require a greater intensity of stimulus to produce reaction than is the case with normal adult fibres. These observations, which confirm the older physiological studies on nerve conduction, have an important bearing on the interpretation of the stimulation results obtained at operation.

It is, of course, only in dealing with incomplete anatomical lesions that the presence or absence of the electrical response is of practical value. Under such conditions various types of response may be elicited—viz., complete silence on stimulation of the nerve both above and below the lesion, a response evoked below the lesion but not above it, and, with the positive reaction above or below, a response limited to the proximal muscle groups only. In interpreting any of these results the period after the infliction of the injury must be considered.

---

* Being an abridgment of the second of two lectures which will appear in full in the British Journal of Surgery.

General Indications for the Choice of the Particular Type of Operative Repair.

We now approach the consideration of the type of operative repair applicable to the individual lesions which may be encountered. Returning for the moment to the classification of the pathological appearances dealt with in an earlier section it is seen that the lesions belonging to the first great group which are in actual fact, or for practical purposes, of a complete anatomical type, can be repaired by the operation of complete nerve suture only. Thus the indications in this group are simple and clearly defined. But in the second group containing a variety of lesions representing wide variations in conductivity it is necessary to consider carefully the arguments for the adoption of any particular form of repair. This involves a separate consideration of the radical procedure of resection and end-to-end suture, and the conservative manœuvres neurolysis and partial resection.

(a) *Indications for resection.*—Resection will be indicated where the extent and nature of the lesion is such as to prohibit a sufficient downgrowth of regenerating fibres to ensure adequate function, motor and sensory. If the operation is undertaken within the period of regeneration it is often difficult to decide in the presence of a negative faradic response in the nerve, and a clinical syndrome of complete interruption, to what extent the lesion is capable of preventing the occurrence of regeneration. The estimation of what constitutes a prohibitive degree of intraneural fibrosis is largely a matter of assumption, and therefore it is impossible to be dogmatic. But a study of cases explored at remote periods shows that certain lesions as a general rule will effectually act as a permanent block. It may be said that in the case of the nerve spindle when the intraneural induration is very dense, and particularly if the spindle is incompletely encapsuled, and connected by sprouts of nerve "callus" to the surrounding tissues, resection is justifiable. The same applies to the other forms of symmetrical lesion. When the operation is conducted at a greater period than six months from the time of the original lesion, resection of the lesion is to be regarded as indicated as a routine where the clinical syndrome is stationary and the electrical response is absent, but it must be admitted that the personal element enters into such decisions to a considerable degree.

(b) *Neurolysis.*—The operation of neurolysis has come to include several distinctive forms of procedure, but should properly be limited to the pure release of a nerve trunk from the scar tissue in its immediate surroundings. It is convenient, however, to consider under this heading every manœuvre which is short of the actual suture of the nerve trunk as a whole or in part. Two distinct variations can be distinguished.

(1) The endo-neurolysis operation introduced by Stoffel,[2] in which an attempt is made to remove the scar tissue between the individual nerve bundles. Such an operation, which makes a strong theoretical appeal, has proved in actual practice to be of little value. The claims made for it by its author have not been enthusiastic, nor are the reported results beyond criticism. In the few cases in which I personally have attempted to do this operation the intraneural dissection has left intact at the end perhaps one or two nerve bundles, so that the problem of the filling up of the remaining gap has at once arisen. It would be fair to say that in the case where endo-neurolysis might possibly be indicated the lesion will either be so small as to produce little interference with the nerve-conduction, and therefore is unlikely to be explored by the surgeon, or will be so extensive as to indicate without doubt the performance of total resection and suture.

A crude variant of endo-neurolysis is the operation of "hersage" of the French surgeons, in which longitudinal incisions are made into the substance of the nerve in order that the containing bundles may be released from the compression effect of the endoneural scar. This operation is obviously of a haphazard type; it has no anatomical boundaries, and is illogical in its conception. It is difficult to see how it can be done efficiently without producing harm. In the recent American literature on nerve surgery it is claimed that no permanent damage has been caused by this operation, and that its results, still to be investigated, are likely to be good. (Babcock and Spear[3].) It is fair to condemn both these procedures and to eliminate the operations of endoneurolysis and hersage from the recognised forms of legitimate nerve repair.

(2) Neurolysis proper, in the actual technique of which simple operation wide variations in detail must necessarily be seen. It has long been a recognised principle that in every operation on an injured nerve trunk the perineural scar tissue should be removed as completely as possible and the nerve restored to a bed closely approximating the normal. Neurolysis then, as a technical procedure, is the usual accompaniment of any nerve exploration in which the slightest deviation from the normal is found in the immediate surroundings of the nerve trunk.

But in connexion with the application of this procedure as the appropriate method of dealing with certain types of incomplete anatomical lesions, the potential or proved effect on the immediate and future conductivity of the nerve must be clearly defined. The rationale of the operation is based on the experience of the classical compression lesions seen in the injuries of nerve trunks in civil life and where the surgical removal of the perineural compressing agent is rapidly followed by the restoration of conductivity or function. But, as has already been emphasised, warfare lesions are primary in origin and the block to conduction intraneural in location. In the production of the loss of conductivity, the perineural fibrous tissue plays a minor or negligible part, and it is difficult to prove that the process of regeneration is delayed or even completely retarded by the continued existence of extraneural scarring. It is still more difficult to prove that after the removal of such external scar the occurrence of recovery is necessarily due to the operation per se. Such proof should be forthcoming from a study of the effects of the neurolysis operations, and would be afforded by a clear demonstration of the rapid return of function, or the appearance of steady recovery after a prolonged stationary syndrome of blocking. The downward march of steady recovery seen over a period corresponding to the time taken by normal or even abnormally slow regeneration, or the ultimate recovery seen in a nerve operation long after the operation, and where no clinical observations on the rate and type of regeneration have been made in the intervening period, is not in any way indicative of the beneficial effects of the operation. From my own observations in a considerable number of the operations classed as neurolysis, such distinctive proofs are not forthcoming. The exact manner in which removal of perineural scar tissue might influence the conditions in the interior of the nerve trunk is also not easy to explain. That a new vascularisation of the immediate surroundings will be promoted is obvious. But, as we have seen, the extraneural vascular supply has little significance in relation to the process of regeneration. Souttar[4] has suggested that the effect of neurolysis is to restore the mobility of the nerve trunk in the area of the injury, and thereby eradicate a factor which is indirectly productive of a continuance of intraneural trauma from the repeated slight stretching of the nerve during the movements of the limb.

It is important to recognise that in the warfare nerve operation the operation of neurolysis has a distinctly limited application if it is to be judged as an entity and regarded as a method of repair competing on almost equal terms with resection and suture. When a lesion of the incomplete type is exposed at operation the decision to be made is whether resection is justifiable, and if this is decided against—that is to say, it is considered that the nerve trunk will show ultimate spontaneous regeneration—the nerve is placed in the best possible surroundings with the expectation that in some way the improved nutritive standard of the bed will help to promote the development of such spontaneous intraneural repair.

Summary.—We may conveniently summarise the position of the neurolysis operation as follows:—

(1) The technical details included in the full scope of the operation are an essential feature of every nerve exploration in an endeavour to provide a normal bed and the local free mobility of the nerve trunk.

(2) The influence of the operation itself in the restoration of future conductivity is difficult to estimate. Owing to the special characteristics of the lesions typical of warfare injuries any operation which is limited to repair of the extraneural lesions is a priori likely to play a subordinate part.

(3) The operation is not an equivalent alternative to resection and suture in any given incomplete type of lesion.

Partial resection and suture.—Reference has already been made to the suggestion that in theory the recognition of a lesion confined to a limited area of a nerve trunk, with an absence of conductivity demonstrated by direct faradic excitation at operation and with the clinical syndrome presenting a paralysis limited to the muscle group which fails to respond, would have afforded opportunities for the trial of the conservative operation of partial resection. From a technical point of view, if this operation is feasible the resulting gap must either be closed by direct suture with inevitable looping of the intact portion or by the insertion of a nerve graft, both procedures which do not fulfil the ideals of repair. The method of partial resection and partial grafting has been advocated by the French school, but the literature offers no detailed reports which can be submitted to a critical examination. Doubling or looping the intact part of the nerve trunk is in no way inherently harmful, and later on disappears, as may be seen at re-explorations after suture of one component of the sciatic trunk. But apart from technical objections, it is certain that the indications for partial resection cannot be clearly defined except in theory, and conditions under which the operation would be feasible are so rarely reproduced in practice that the operation may be eliminated as a standard method of nerve repair.

Difficulties in obtaining End-to-End Suture.

It is necessary to return to a review of the difficulties which are so often encountered in the attainment of the end-to-end apposition which precedes the actual suture.

1. *Mobilisation and relaxation of the nerve.*—Of the methods employed to surmount these difficulties, some have established themselves as legitimate steps in the operation technique about which there can no longer be any question of conflicting opinions. These are the widest mobilisation of the nerve afforded by the most extensive anatomical exposure, the stripping or even the sacrifice of muscular branches, such displacement of the nerve as will shorten its course, and the relaxation obtained by the appropriate changes in the posture of the limb. Such measures will enable almost every gap to be closed and the number of true irreparable lesions will then be small.

2. *The two-stage operation.*—If end-to-end apposition fails at the first exploration it is legitimate to re-explore after an interval. The two-stage operation, in which the untrimmed ends are anchored by sutures, and rapid stretching is carried out over a short period, is sound in theory, and certainly in practice seems to facilitate the achievement of suture, but in my opinion not for the reasons generally attributed to it. There is really little, if any, true stretching of the nerve trunk during the intervening period, and the actual gap does not diminish. In my own two-stage operations I have been struck by the fact that the anchored stumps have rapidly become fixed to the surrounding tissues at a time before the condition of the patient and limb has allowed stretching to begin. In a certain number of cases re-exploration has to be postponed for a period beyond that during which the hypothetical stretching is completed.

In the sciatic nerve, for which the two-stage operation is especially useful, the long tedious primary operation which is often provocative of a considerable degree of shock, and is followed by considerable post-operative pain and discomfort, can rarely be repeated within a few weeks.

I would suggest that the success obtained in the two-stage operations is due to the fact that instinctively a wider exposure of the nerve is made, and this with the sheer determination to effect repair, plays a dominating part. I am confident that this is the correct explanation in the successful two-stage sutures in my own operations. In fact, the period between the two explorations can be prolonged with advantage, as the intensive physio-therapeutic measures applied during the interval undoubtedly can produce a greater degree of softening and extensibility in the tissues of the limb.

3. *Bone shortening.*—There remains to be considered one other procedure which has been freely advocated—viz., the operation of bone shortening. It should be said at once that to this method there are serious objections. It belongs essentially to the type of operation which depends for its popularity on pictorial representations which appeal to surgeons who are inexperienced or ill-trained in the technique of reconstructive surgery. In the limb in which an extensive gap in an injured nerve trunk is found the coexisting injuries of the soft parts and often of the bony skeleton are sufficiently grave to render the operation mechanically difficult and provocative of a recrudescence of sepsis. In the lower limb the operation is to be condemned under any circumstances. In the upper limb it is justifiable for one indication only, and that is where an ununited fracture of the humerus accompanies a musculo-spiral nerve injury, and where bone shortening, the performance of the recognised stepcut operation, is a necessary preliminary to exploration and suture of the nerve.

4. *Bridge operations.*—In the few operations where, in spite of the measures indicated above, end-to-end apposition is still unattainable the lesion must be written off as irreparable by the method of direct suture. At this stage the divergent views of two schools are to be examined. On the one hand, the idea of nerve repair is abandoned permanently and recourse is had to those alternative methods for the restoration of function, which involve plastic operations on muscles, tendons, or joints. On the other, the gap in the nerve trunk is to be filled by the insertion of some form of bridge across which it is hoped or claimed that regenerating fibres will travel. Perhaps no one section in the surgery of nerve injuries has excited so much interest and discussion as the question of the utility of the various forms of bridge operations. Such are neuroplasty (repair by flaps), nerve grafts, and tubulisation, and though not in the strict sense a bridge operation, the various forms of nerve crossing.

(a) *Flap operations.*—This operation, illogical on physiological grounds and proved to be totally incapable of facilitating regeneration in experiments, has received its final deathblow in a recent review by Stookey[5] of the published results in the whole of the literature of nerve surgery.

(b) *Nerve grafts.*—The nerve graft has long held an honoured place in the surgery of peripheral nerves and during recent years has been extensively employed. It has been an acknowledged fact that axis cylinders can cross a gap and may utilise existing channels afforded by the graft. This is shown quite definitely in the modern histological work of Lewis,[6] Nageotte,[7] and Ingebritgsen.[8] But as a method of practical repair the operation will be judged by its capacity for the conveyance of such a large number of axis cylinders as will invade the distal trunk and ultimately function. From this viewpoint a clear distinction must be drawn between the various types of graft operation. Those practised are the single small trunk graft, multiple or cable grafts, and the single large trunk graft. The autogenous or homogeneous nature of the transplants does not appear to influence the fundamental question of their utility. Other things being equal, the large trunk graft or cable grafts which provide opportunities for the crossing of the total number of axis cylinders of the injured nerve should be superior to the single cutaneous graft of small calibre. This latter technique has, perhaps, been the common routine in nerve surgery and particularly in this country, whereas in America and France the use of cable grafts and large homogeneous trunk grafts has been the rule. In reviewing the recorded results of these operations in an attempt to estimate their functional value, if any, it is important to recognise these quantitative differences in the technique. In the warfare literature, successes have been reported in nerve grafts particularly by the French School of Surgeons (Sencert). In this country Joyce,[9] Forrester Brown,[10] and others have recorded cases in which restoration of conductivity has been exhibited, and in the addendum of the report of the Medical Research Council details are included of two cases in which success was confirmed by members of the committee. Dean Lewis (loc. cit.), whose contributions to nerve surgery have been amongst the most authoritative in the American literature, has seen slight return of motor power in 2 out of 12 cable graft operations.

A year ago I reported[11] the complete failure of 18 bridge operations performed in my series which had been studied over varying periods extending up to two years, and of which 11 were examples of nerve grafting in which a single cutaneous graft had been used. From the additional evidence derived from the re-exploration of four and the histological examination of one resected graft it was urged that the operations from a practical standpoint were to be considered as failures, and the re-exploration of all bridge operations was advocated where at a second attempt end-to-end suture would be feasible. Since then a further number of these bridge operations have been re-explored, making six in all, and in addition one has had an opportunity of resecting two grafts inserted by other surgeons. My colleague J. S. B. Stopford[12] has examined seven additional cases, all of which have shown failure of recovery. From the appearances revealed in my secondary explorations of five grafts the hypertrophy of the grafts described by various observers (Joyce, Lewis, and Forrester Brown) was not confirmed.

This experience caused me to range myself alongside those who have unhesitatingly condemned the use of nerve grafts. But the recent secondary exploration of one of my cases three and a half years after the insertion of a graft for an ulnar nerve injury in the forearm has provided me with an interesting and instructive experience. When the nerve trunk was fully exposed a definite response was elicited in the hypothenar muscles and adductor pollicis from stimulation of the nerve above, below, and in the area of the graft. This particular graft had retained its original calibre, and at each extremity there was a slight enlargement of the nerve trunk, but without any obvious induration. The original fascial sheath was recognised closely enveloping the area of the bridge. In view of the electrical findings it was decided to leave this nerve *in situ*, and a careful examination of the patient since the operation shows that it is possible to recognise the existence of a very slight recession of the area of protopathic loss in association with a positive Tinel's sign. The ulnar intrinsic muscles are still completely wasted as before, and the external electrical tests gave the typical sluggish galvanic response only.

It is not to be questioned that conduction can be established through nerve grafts, but it should be realised that even for incomplete success the operation must provide a passage for a considerable number of motor and sensory fibres. In anything less than restoration of the full calibre of the nerve trunk the chances of a useful regeneration are small. It is therefore in the future to the reports of the results of the operations of cable grafts or homogeneous large grafts that we may look for confirmation of their value. Until such reports are forthcoming condemnation of these procedures, not on physiological grounds, but as practical manœuvres is still reasonable.

It is further essential to discourage the half-hearted attempts at obtaining suture in difficult cases which are likely to be characteristic in the future of the technique of the inexperienced surgeon who is comforted by misleading and enthusiastic reports of the value of the operation of nerve grafting.

(c) *Tubulisation.*—The operation of tubulisation demands brief reference only. Successful in animal experiments, it has proved a complete failure in nerve surgery, and this has been commented on in the literature from all countries (Dean Lewis, Platt, Stracker, Wollenberg[13]).

(d) *Nerve crossing.*—The probable failure of the operation of incomplete nerve crossing (nerve anastomosis) has already been foreshadowed in the earlier part of this paper. Of the examples of incomplete distal anastomosis performed elsewhere which have passed under my notice, in all the distal end of the ulnar nerve had been implanted into the median. These patients have been carefully examined on repeated occasions by Stopford, who has demonstrated in all not only complete failure of regeneration, but the interference in the conduction in the median nerve which had directly followed the operation. In four of these the ulnar nerve has been re-explored, divided at its junction with the median trunk, and end-to-end suture obtained.

In my opinion this operation should be condemned in no measured terms.

GENERAL CONCLUSIONS ON THE POSITION OF BRIDGE OPERATIONS.

It is reasonable to emphasise that the recorded success of a small number of operations of the bridge class should not be allowed to influence the surgeon in the direction of relaxing his efforts to obtain end-to-end suture, no matter how exhausting and tedious any operation may be. The two-stage operation should be considered as an established method, and if failure is again experienced at the second attempt the gap may be legitimately closed by the insertion of a full-size graft or cable graft; but at the best little or no recovery can be expected. Under such circumstances, after a prolonged period, and if an alternative operation of equivalent functional value is available, as in the case of the musculo-spiral nerve injuries, this should be performed without further delay.

RESULTS OF OPERATIONS FOR THE REPAIR OF NERVE INJURIES.

Analysis of a Personal Series of Operations.

General survey.—In Table I. is shown an analysis of the total operations performed in my services over a period extending from March, 1915, to December, 1920. They may be taken as representative of an average individual operative experience, and it is therefore safe to refer briefly to certain general information that the statistics themselves afford. In the first place it is seen that the ulnar nerve has dominated the whole surgical field. Further, the infrequency of the operations on the brachial plexus and the complete absence of any operation on either the musculo-cutaneous and circumflex nerves in the upper arm, or the anterior crural nerve in the lower limb, are facts to be noted but requiring no special comment. In the various types of operation the phases through which the operator passed are illustrated in the large number of operations of the bridge type and those in which repair was abandoned.

Analysis of Results.

Of the operations in this series it has been possible to investigate the early and later results over periods extending from six months onwards in 247 only.

It must be admitted at the outset that this study includes few if any *true* end-results. The most reliable records in our possession are those accumulated on the operations performed since 1917, when the advantages of a more efficient segregation of the patients, and the inauguration of the follow-up system were available. But even under conditions which from the point of view of civil surgery might be considered ideal, the greater number of the patients could be kept in hospital for short periods only, and ultimately were distributed in various parts of the country. This difficulty has been experienced by all surgeons working in this field, and it explains the comparative paucity of the operation statistics produced in this country up to the present date. But the same deficiency is seen in the literature of the European countries. From America, however, where practically every nerve injury was sustained in 1918 and the prompt segregation of all patients was effected from the beginning, and where the operations were carried out under conditions of less physical strain, valuable contributions should be forthcoming in the near future.

In this post-operative study the presence or absence of signs of recovery have been recorded after personal examinations only. Whilst many patients living at a distance have from time to time replied to inquiries as to their progress, the inclusion in their reply of suggestions indicating recovery or otherwise have always been ignored. It is perhaps unnecessary to stress the fallacies of conclusions drawn from such impersonal investigations; my excuse is that one has occasionally seen in the possession of out-patients forms which were to be filled up recording the impressions of the man himself on the alterations in the sensory and general functional condition of his limb.

The 248 operations from which information as to results have been available include, the following: end-to-end suture, 150; neurolysis, 80; bridge operations, 18. The results of the bridging operations have already been alluded to in the general exposition of the technique of operative repair, and therefore demand no further consideration.

Results of End-to-end Suture—150 Operations.

My colleague, Stopford,[14] issued a year ago a preliminary report based on a study of 271 suture operations, and in his series included the bulk of my own operations up to date, in addition to the observations made on a considerable number of our out-patients who had been operated on in other surgical centres. The experiences of a further period of

Recovery, 118 (79%); failure, 32 (21%).

12 months have allowed one to collect additional evidence concerning the fate of a considerable number of the patients with whom we have been in touch. It is a simple matter to accumulate a mass of details in the case of each patient under observation which are interesting to the individual neurologist or surgeon, but it is not an easy task to concentrate them into skeleton form. At the same time, however desirable broad conclusions accompanied by figures representing percentages of this or that type of recovery may be, the lessons of failure, which, as in all surgery, form the real foundation of teaching, can be acquired only from a consideration of each individual case in full detail. Such can hardly be presented in the limits of this lecture.

In the accompanying tables are shown the figures illustrating the frequency and type of recovery in nerve suture. The recovery of motor function is divided up under the headings of the proximal and distal muscle groups, a classification which is found to be convenient, particularly for the upper limb. In the whole series there are no examples of absolutely complete and perfect recovery excepting possibly in five of the musculo-spiral and two of the external popliteal sutures. The operations in which the existence of recovery is charted include every variety and type of incomplete restoration of conduction in the sutured nerve. It is not considered a logical procedure to classify such recoveries into further arbitrary special divisions, such as "slight," "marked," and so on, for the simple reason that the periods of post-operative observation are not constant for any one group of allied operations. This is strikingly illustrated by the figures for the musculo-spiral nerve, where in the first column, the majority of the patients were examined at an interval less than one year (with two exceptions), in the second column under 18 months (two over 2 years), and in the third all over 18 months. To a lesser extent this applied to all other nerves, and it indicates, that given long periods of time, many of the imperfect recoveries of to-day will progress, or have already progressed, towards the stage of complete recovery. The standard of failure adopted in my analysis is the existence of complete and stationary absence of recovery after a year or more, and in some cases confirmed by the evidence of re-exploration. With regard to the sensory recovery noted, as a whole, in very few cases has there been more than a slight recession or incomplete restoration of protopathic sensibility.

The information and conclusions as to the late results of suture may best be embodied in a consideration of the main factors which have determined, delayed, or entirely prevented success.

1. *Period of delay between original injury and performance of the operation.*—In my own series the influence of the time factor has been definitely proved. As a general rule sutures performed within a period of 18 months show little appreciable differences in the time of the onset of recovery or the rate and ultimate completeness of the recovery. After a delay of two years recovery is often seen to be tardy, incomplete, or in some cases fails completely. This truth has long been established as a fundamental factor in prognosis in the older nerve surgery (Kennedy[15]). My records show what has been pointed out in Stracker's careful analysis of the operations performed in the clinic of Hans Spitzy, of Vienna, that the degrees of delay within the safe period does not influence the percentage of cases showing recovery, but does seem to prejudice the ultimate quality and type of the regeneration. In the complete failures, quite apart from other influences, the time factor plays an important part. It is assumed that this is dependent on the development of permanent retrogressive changes in the spinal cells and to a much lesser degree to peripheral degenerative changes in the muscles. On the other hand, in the analysis of the operation results in the service of Sir Harold Stiles, of Edinburgh, it would appear that this factor has exerted a negligible influence (Forrester Brown).

2. *Recrudescence of septic infection in the limb.*—The recrudescence of infection at a period after the suture has been seen in a number of the cases in my series. Where this has arisen spontaneously it does not appear always to have affected the regenerative process, but it has been my fate to see a definite recession in the regeneration which had already begun, after the exploration of an associated ununited fracture, followed by infection. This unfortunate sequela, due to imperfect surgical judgment, is one which could have been avoided, and, perhaps, is hardly to be cited as a fair test of the resistance or lack of resistance to sepsis of the regenerating nerve. In the recovery stage of a number of sciatic nerve sutures the trophic ulceration seen under the base of the fifth metatarsal or in the terminal phalanx of the great toe where definite necrosis has resulted provides a continued source of infection which might conceivably be absorbed and travel upwards towards the area of suture. Delay or cessation in recovery has been invariably associated with this complication, and I would suggest that it is in some way connected with the absorption by the regenerating nerve of distal sepsis.

3. *Anatomical situation of suture.*—The distance of the line of suture from the spinal centres, or conversely from the distal extremity of the limb, is seen to be an important factor in determining the fate of the regenerative process. This is illustrated by a study of the time of onset of the appearance of recovery in the muscles supplied at successive levels, and in a comparison between the results of suture in the proximal and distal parts of the limb respectively.

The times of the appearances of recovery in the chief muscle groups have been carefully charted in Stopford's recent contribution, and are seen also in Stracker's monograph. Recovery in the proximal muscles begins at an early or later date according to the proximity of the suture to the spinal cord, and occurs in regular descending fashion in accordance with the anatomical origin and distribution of the motor branches. Thus, for example, after suture of the musculo-spiral nerve in the upper, middle, and lower third of the arm, return of power is manifest in the supinator longus at about the seventh, sixth, and fourth months respectively. Distal recovery also shows these differences in time relation.

In Stracker's figures[16] no recovery was seen before one year after suture in the distal muscles of the musculo-spiral, median, or ulnar supply, and this irrespective of the level of the suture. On the whole this is borne out by the records of my own operations. Thus the time taken in neurotisation of the distal muscles is not entirely dependent on the distance which downgrowing axons have to travel. It has been concluded from this that the results of suture are better in the proximal part of the limb than in the distal. Stracker states that in general sutures below the origin of the proximal muscle branches give bad results. This would appear to be correct as a broad statement, but on careful examination requires certain qualifications. If the results of suture of the median and ulnar nerves in the upper arm and forearm are compared as regards distal recovery alone, both motor and sensory function combined, which means that a period of 12 months at least must have elapsed, the quantitative recovery appears to be roughly equal in each group.

4. *Influence of topography.*—The inaccuracies of regeneration due to the shunting of motor fibres along sensory channels and vice versa are undoubtedly one of the causes of imperfection in the recoveries and may be of such a degree as to determine complete failure. It has been impossible in a close perusal of one's operation records to correlate in each case the potential influence of this factor with the type of recovery seen. In the sciatic nerve sutures it has been easy to retain an accurate topography, whilst in the musculo-spiral the comparatively scanty sensory bundles, even when misdirected, have not prevented the transmission of a large proportion of motor fibrils along appropriate channels. The exact rôle of topographical errors as applied to the individual operations cannot be settled until it is possible to examine a large number of successful sutures of the median and ulnar nerves after a period of three years or more.

In certain situations—e.g., in the lower half of the forearm where suture of either the ulnar or median nerves has been achieved with what might be claimed as faultless topography, one has had little direct proof of its beneficial effect. Topographical failure is best illustrated by the suture of a nerve of smaller calibre to a larger trunk, as in the case of suture of the posterior interosseus to the musculo-spiral and of the anterior tibial and musculo-cutaneous to the external popliteal, operations which account for eight cases traceable in my series and in all of which complete failure resulted. The topographical factor in regeneration is, however, usually cited as an illustration of the apparent superiority of the results of suture of the musculo-spiral nerve over those of the median and ulnar nerves and of the delay or absence of recovery in the distal muscles.

5. *Influence of perineural surroundings.*—The nerve bed. It does not appear from my own observations that the perineural surroundings have influenced the occurrence of recovery after nerve suture in any way except in a few cases where the nerve trunk has been subjected to the friction of a bony groove, as in the case of the ulnar at the elbow, or has been left in close relation to bare tendons—e.g., median suture at the wrist. The deleterious effects of a nerve bed of this type have contributed to the complete failures of one ulnar and one median suture, but failures of this type are to be regarded as preventable with a more efficient technique.

6. *Influence of complications.*—(a) Vascular. In a number of upper arm sutures of the median or ulnar nerves, or both, where ligature of the brachial artery has been performed in the early days of the injury, there has been little appreciable effect on the rate and degree of recovery. Where contractures and other signs of ischæmia have coexisted and the total mechanical disability is naturally great, the

clinical evidence of the recovery of the nerve has often been masked.

(b) Non-union of fractures. The continued existence of non-union of a fracture without active inflammatory signs in the neighbourhood of the recovering nerve has retarded or prevented recovery in two musculo-spiral sutures in my series; one showed a failure of distal regeneration after four years; and the other, a total absence of any sign of recovery. The cause of these failures is to be attributed to the effect of tension and friction.

7. *Continuance of active interstitial neuritis in the proximal nerve.*—This is a potent cause of delay or failure which theoretically is avoidable by a free resection preparatory to suture. But it is certain that histological evidence of interstitial change may often be present in the proximal part of the nerve trunk when there is little or no macroscopical sign of its existence. Where there has been a long delay owing to the presence of inveterate sepsis in the limb the interstitial neuritis finds its maximum development. In my own operations complete failure or imperfections in recovery have been dependent on this factor, and particularly in the sciatic nerve, where the ill-effects are manifested during the stage of tardy recovery by the development of the signs of irritation. In three cases, after a period of more than two years, the pain in the internal popliteal distribution is a most serious handicap to the patient, and continues to defy every form of treatment. On the other hand, in one of the complete recoveries after musculo-spiral suture, definite evidence of interstitial neuritis was seen in the proximal part of the nerve trunk at the time of operation, and owing to the size of the gap the suture was performed at a level which was considered far from ideal.

It now remains to judge the results of these nerve sutures from a qualitative standpoint. In this estimation it is necessary first of all to eliminate from the total disability of the limb the contribution of the coexisting injuries of other tissues. But function dependent on a restoration of nerve conductivity alone is itself essentially complex. Success depends not merely on the simple restoration of adequate motor and sensory conduction, but on the development of coördination in the particular movements, in which the efferent and afferent supply of the sutured nerves are concerned. In the musculo-spiral sutures, where full conductivity has been restored, and where recovering muscle groups have achieved considerable power, there has been as yet no perfect individual extension of the fingers, no synergic function in the extensor muscles of the wrist, and there is on the whole an imperfect control over the extensor muscles of the thumb.

In the median nerve poor function has been the rule, chiefly owing to the very limited sensory recovery. The helpless anæsthetic index finger which is characteristic of most of these cases long after the operation is a striking illustration of the importance in function of a restoration of the median sensory mechanism. In the ulnar nerve, where there is often a mobile hand without contractures, the gross function is little diminished even in the presence of a complete syndrome of interruption, and full restoration is of little moment except for the skilled worker. To many of these hands the addition of conductivity in the ulnar nerve has made little or no difference in function. The full sciatic syndrome in itself does not cause gross loss of function in the lower limb as regards the act of walking. It is difficult to estimate the increased value of the motor recovery, which at the best has been moderate power in the calf and a less complete and powerful action in certain muscles of the extensor group.

Results of the Operation of Neurolysis.

Whilst it is possible to study the results of end-to-end sutures in a truly mathematical fashion, a scrutiny of the results of the operation of neurolysis is beset with many difficulties. It will be sufficient to reiterate and amplify from a consideration of the results in 80 cases what is regarded, in my opinion, as the legitimate scope of this operation.

In the results are seen both recoveries, partial and complete, and complete failures. There have been no rapid recoveries within the period of nerve regeneration, for the type of lesion in which this might have occurred has not been explored. Where recovery has been seen it has been on the conventional lines of the ordinary regeneration as regards time and general progress. A certain number of operations have been premature explorations for lesions of a low grade, in which spontaneous regeneration was at the time proceeding. Where failure of recovery has occurred the intraneural changes have been of such a nature and extent as to inhibit the downgrowth of regenerating axons, and the extraneural operation has failed to alter the intra-ural conditions. Whilst improvement has occurred in the urological syndrome after the operation of neurolysis, in er cent. of cases it has been impossible to prove that the ation itself alone has determined this.

r these reasons I would urge that the limitations of the ation of neurolysis as a definite factor in the surgical treatment of the warfare lesions of nerves are to be fully realised.

Results of operation for causalgia.—My series includes 25 operations performed for severe causalgic manifestations, 14 on the median nerve, 10 on the sciatic nerve, and 1 on the internal popliteal nerve.

General Conclusions on the Late Results of Nerve Operations.

References have been made from time to time to the results quoted in other contributions in the literature of the peripheral nerve surgery of the war. From this literature, already vast, it has been impossible to collect and compare on any recognised standard the total statistics as to the late or end-results of the various forms of operations. From a wide study of this literature, and a personal intensive study of one's own material, it is possible merely to enunciate broad generalisations, influenced in particular by the consideration of the causes of failure and success.

During the past year it has become increasingly difficult in this country, at any rate, to keep in touch with the patients who have been operated upon, even during the last two years. The chances of an acquisition of further comprehensive knowledge regarding true end-results would therefore seem to be slender. This is a bitter disappointment after the labours of a number of years. But, for some little time, a small stream of patients with nerve injuries still unoperated on, or showing failure after previous operation, will continue to flow into the surgical centres of the Pensions Ministry. Such patients, on the whole, are now undesirous of submitting to operative procedures. But the surgical lessons gained from the amount of experience behind us are yet to be applied for the benefit of a few. And it is of great economic importance that clear indications as to the advisability at this date of the exploration or re-exploration of the injured nerves should be laid down. Every lesion will date back at least two years, so that the optimum period for the surgical repair of the nerve is now past. But for perhaps a year longer it will be worth while advising operation in selected cases. Before doing so the economic value of the restoration of nerve conduction to the future capacity of the limb must be gauged. In many limbs an operation is now a waste of time. From a serious consideration of this problem, which is entering into one's surgical work at the present time, it is suggested that the exploration or re-exploration should be considered under the following conditions:—

1. In complete lesions of the median or ulnar nerves in the upper arm. The restoration of function in the proximal muscles is to be expected, even after long periods of delay, but distal recovery may probably not take place. For lesions of those nerves in which conduction is already present as far as the proximal branches with the total failure of distal regeneration, exploration is on the whole advisable, but short of resection and suture, which may be unjustifiable, nothing can be done.

2. In complete lesions of the median and ulnar nerves in the forearm. The potential restoration of sensation in the median is of such great importance as to warrant every effort to be made to ensure its occurrence. In lesions of the median in which partial sensory conduction is present, but with complete motor loss, resection and suture at this date should be strongly condemned. For the ulnar, where the intrinsic muscles are alone inactive, resection is always worth while.

3. In all complete sciatic lesions where end-to-end suture can be reasonably expected.

4. In musculo-spiral lesions exploration of the nerve should precede the performance of tendon transplantation.

Alternative Operations.

Although a technical consideration of those alternative operations for the restoration of function when nerve repair has been deliberately abandoned, or has failed to ensure conduction or function, is outside the scope of the present study, the question of the appropriate time and indications for their exhibition is one which is intimately concerned with the observations of the failures and successes of the suture operations.

Where the nerve lesion is declared to be irreparable after an exploratory operation the indication for the performance of an alternative operation is clear. But in the case of imperfect function following the incomplete restoration of conduction the rôle of the alternative operation cannot be so readily defined. Many of the operations performed under the latter heading have been premature and have been done early in the reconstructive surgery of the war when the normal prolonged stage of recovery of the injured or repaired nerve was not fully realised. The capacity for regeneration and ultimate function of the nerve after repair is apt to be minimised. Every surgeon who has lived close to this problem must have felt at times despondent. The immediate failures or late failures are easily explained and many of their causes in the future can be avoided. It is likely from what we have seen of the behaviour of the regenerating nerve, that after long periods of time, in a considerable number of instances, there will be well-marked recovery of function. It is to be admitted, on the other hand, that to wait for a future recovery of uncertain value is likely to be unsound. Again, the alternative operation itself may in no way jeopardise the recovery of the nerve, and therefore little harm can be done by its early performance. Few of the alternative operations have entered permanently into one's surgical repertoire. In the upper limb these are, above all, the now classical operation of tendon transplantation for irreparable musculo-spiral injuries, the results of which are extremely gratifying; the simple tendon transplantations for restoration of flexion of the fingers or thumb in median and ulnar injuries; and in the lower limb the destructive operation of tenodesis of the ankle as an alternative to the lifelong wearing of apparatus. A new procedure has recently been added to the alternative operations which belongs to peripheral nerve surgery itself. This is the implantation of the proximal end of the radial nerve into the median nerve at the wrist—an attempt to restore that lost sensory function in the median area which produces such a grave incapacity. This operation was introduced by Harris,[17] of Toronto, and is supported by the report of one successful case. For the few irreparable lesion of the median nerve in the forearm this operation may be worth a trial.

I am indebted to a number of colleagues for their invaluable coöperation in the work upon which these lectures have been founded—to Professor Stopford above all, to Mr. E. S. Brentnall, and to Dr. E. H. Linell. Finally, I owe to Sir William Thorburn, my former chief, my early training and interest in peripheral nerve surgery, and to Sir Robert Jones the opportunities afforded for this work in the surgical direction of a special hospital.

RESEARCHES ON THE BIOCHEMISTRY OF GERMS AND OTHER PROTEINS.

WITH SPECIAL REFERENCE TO THE PROBLEMS OF IMMUNITY.

BY DAVID THOMSON, O.B.E., M.B., CH.B. EDIN., D.P.H. CAMB.,

LECTURER AND RESEARCH PATHOLOGIST, LONDON LOCK HOSPITAL.

PART I.—THE SPLITTING OF GERMS AND OTHER PROTEINS INTO THEIR COMPONENT PARTS.

1. *Preliminary Note.*

THE history of man's research on the human body and its diseases has shown a definite series of stages, wherein he has passed from the gross to the minute and from the minute to the microscopic. We are now advancing rapidly to the study of the ultra-microscopic, a study which is all-important to our further progress. Anatomy led to pathology, pathology led to histology and to bacteriology, and bacteriology in its turn has directed us to biochemistry. The dominant importance of these previous stages may not be gone for ever; when those who come after us have analysed more finely still these mysteries of nature, man will no doubt turn again to study the process by which from the infinitely fine the grosser substance is built up.

2. *Introduction.*

The biochemical researches which I am about to describe were commenced in the early part of 1917. At that time I was engaged largely in growing the gonococcus and in making large quantities of gonococcal vaccine for the army.

The gonococcus is a germ which undergoes autolysis or disintegration very readily. On certain culture media the cocci swell up and fuse to form a viscid material, in which *no discrete* organisms can be distinguished. After many experiments carried out to ascertain the cause of this phenomenon I eventually discovered that *gonococci are very readily soluble in dilute alkalis*, such as normal or even decinormal sodium hydroxide; suspended in an alkaline urine they disappear or melt away in a few hours, but in an *acid urine they remain distinct and discrete* for many months. Thus when emulsified in Na_3PO_4 solution, which is strongly alkaline, the germs rapidly dissolve; in Na_2HPO_4 solution (slightly *alkaline*) *they autolyse more slowly*, while in NaH_2PO_4 solution (definitely acid) they remain discrete and unchanged. These facts impressed me very strongly, and I eventually found that if a considerable mass of gonococci is treated with an equal volume of N/1 NaOH, the mass completely dissolves *in a few hours*, to form a yellowish syrupy fluid. Solution is brought about more *rapidly* with gentle heating. By adding an acid such as N/1 HCl to this alkaline solution, it is possible to bring it to a state of neutrality without any apparent change. I made use of this neutral gonococcus solution as an antigen in the complement-fixation test for gonorrhœa, and it *worked very well* (*D. Thomson*,[11] 1918, confirmed by W. Magner[6]). These researches showed that the *germ* can be dissolved in alkali without thereby altering its antigenic properties. When an *alkaline or neutral solution* of the gonococcus is boiled for five minutes it does not coagulate, and it still *remains* a tolerably good antigen. When boiled for 30 minutes or longer, however, its *antigenic properties* are largely destroyed.

When an alkaline solution of gonococci is *neutralised* with N/1 HCl and then rendered definitely acid to litmus, a heavy white *precipitate* is *thrown down*. At first I believed that the gonococcus was largely composed of a fatty substance which was *saponified* and dissolved by the alkali, and that the precipitate thrown down by acid *consisted of a fatty acid*, but it was subsequently proved that the precipitate was a protein substance.

3. *First Attempts at Producing Detoxicated Vaccines.*

Having ascertained that the gonococcus substance (thrown out of solution by acidification) is antigenic, I commenced to test the therapeutic value of this precipitate by subcutaneous injections in gonorrhœal subjects. It was found, *after many injections*, that the precipitate was some 50 times less toxic than the *actual* untreated gonococci themselves. Moreover, the larger doses of the non-toxic precipitate appeared to confer more immunity and gave better therapeutic results than the necessarily smaller doses of the untreated germs.

In order to test scientifically the relative value of the non-toxic precipitate and *the ordinary toxic vaccine* in the production of immunity I made use of the complement-fixation test. A large number of such tests were carried out in four parallel series of patients, and clinical *observations were carried* out simultaneously by the same clinician (Lees,[4,5] 1919).

Series A, in which the gonorrhœal subjects received no vaccines, showed on the average *three units of immunity* acquired naturally in the course of the disease.

Series B received ordinary gonococcal vaccine in doses of 5 to 100 million germs, and developed about four units of immunity.

Series C received ordinary gonococcal vaccine in doses of 25 to 200 million germs, and developed an average of five units of immunity.

Series D received the non-toxic precipitate in doses corresponding to 2000 to 10,000 million gonococci, and developed as a rule 8 to 12 units of immunity.

Further injections of the comparatively large doses of the non-toxic gonococcus precipitate into normal subjects rendered their blood positive to the disease, whereas the necessarily small doses of the toxic untreated germs had no such effect. (Thomson,[13] 1919, and D. Lees,[4] 1919.) These immunisation experiments have been more or less repeated and confirmed by H. B. F. Dixon and A. H. Priestley[5] and by W. V. Corbett and T. E. Osmond.[2]

4. *The Toxic Material from the Gonococcus.*

Having ascertained that the gonococcus protein precipitate[*] thrown down by acidification (from the original alkaline solution) was comparatively non-toxic it naturally occurred to me that the toxic properties of the germ would be found in the acid supernatant fluid, which was separated from the precipitate by centrifuging or by filtration. This belief proved to be correct; small doses of the supernatant fluid caused quite an intense local reaction when injected subcutaneously. The acid supernatant fluid was neutralised before injection, so that the local reaction produced was *not due to the acidity of the fluid. This supernatant* fluid has also a provocative effect in the disease, since it increases the symptoms and renders the urethral discharge more profuse; it was found to contain protein substances which can be precipitated by the addition of picric acid, ammonium sulphate, or absolute alcohol.

5. *Parallel Researches with other Proteins.*

These preliminary researches on the gonococcus led me to a similar study of other pathogenic organisms and of proteins in general. First of all I carried out a series of parallel experiments on germ protein (gonococcus), animal protein (ox heart), and vegetable protein (pea flour). The gonococcus, minced ox heart, and pea flour were easily soluble in N/1 NaOH, but a certain proportion of undissolved substance remained which could be removed by filtration.

Table I. shows the salient results of this investigation.

TABLE I.

Tests applied to minced ox heart.	Tests applied to gonococcus.	Conclusions.
N/1 NaOH added—Mince dissolved after standing 12 hours at 37·5° C. Distinct odour of ammonia.	N/1 NaOH added—Germs dissolved after standing 12 hours at 37·5° C. Distinct odour of ammonia.	Similarity in both.
Alkaline meat solution gives biuret, xanthoproteic, Millon, and other protein tests.	Alkaline germ solution gives biuret, xanthoproteic, Millon, and other protein tests.	Both solutions consist largely of alkaline meta-protein.
On neutralisation with N/1 HCl a heavy precipitate is thrown down giving a straw-coloured supernatant fluid which is decanted or filtered off.	On neutralisation with HCl a heavy precipitate is thrown down, giving a straw-coloured supernatant fluid which is decanted off.	Similarity in both.
In both tests the precipitate is easily soluble in N/10 NaOH and gives the protein tests. It is insoluble in neutral H_2O, neutral alcohol and ether.		Both precipitates consist of meta-protein.
In both tests the precipitate is readily soluble in 50 per cent. acid alcohol.		Similarity in both.
In both tests the supernatant fluid or filtrate gives the protein tests and yields a precipitate on half saturation with ammonium sulphate and with 70 per cent. alcohol. This precipitate is partly soluble in water.		Both supernatant fluids contain protein resembling proteose.†
In both tests the supernatant fluid from the primary proteose gives the protein tests and also a precipitate on full saturation with ammonium sulphate and also with excess of absolute alcohol. The precipitate is almost completely soluble in water.		Both supernatant fluids contain protein resembling deutero-proteose.‡

N.B.—All of the above tests apply equally, except for some very minor differences to the pea flour.

From these tests it appears very evident that the meat (ox heart), the gonococcus, and pea flour are very similar in nature, and that all three substances consist largely of protein, which can be split up into meta-protein, primary proteose, and deutero-proteose. The non-toxic gonococcus vaccine, already described, consisted of gonococcus meta-protein, and it is now evident that the toxic supernatant fluid contained primary and secondary gonococcus proteose.

6. *Antigenic and Therapeutic Values of the Gonococcus Proteoses.*

Having reached this stage of the investigation, one was naturally curious to know whether or not the gonococcus proteoses were the cause of the toxicity of the supernatant fluid already referred to in paragraph 4.

Experiments on gonorrhœal subjects showed that the primary and secondary proteoses from the gonococcus were no more toxic than the comparatively non-toxic meta-protein itself. They produced no marked local or general reaction such as fever and malaise. It was, however, noted that an injection of these proteoses caused quite a definite provocative reaction at the focus of the disease. Thus, when there was an existing urethral discharge a subcutaneous injection of gonococcus proteose caused an increased flow of pus within the next 48 hours; a return of discharge after the latter had dried up, or an increase of shreds in the urine of chronic cases, were also often induced in the same way. For these reasons a subcutaneous injection of the proteoses has been found useful as a provocative test of cure in gonorrhœa. In gonococcal iritis an injection of the proteose may cause an acute flare-up in the eye; it is, therefore, not recommended as a diagnostic test in this condition.

A certain amount of immunity appears to be developed against the proteoses, since after repeated injections they lose their focal provocative action. Moreover, I found that the primary and secondary proteoses were antigenic, as they gave positive results when used as antigens in the complement-fixation test for gonorrhœa. They appeared to be good antigens when precipitated with alcohol, and comparatively poor antigens when precipitated with ammonium sulphate. It is just possible that the ammonium sulphate alters them in some way.

7. *Alkali Solubility of other Germs and Proteins.*

Having ascertained that the gonococcus is easily soluble in N/10 to N/1 NaOH, and that minced meat is easily soluble in N/1 but scarcely soluble in N/10 NaOH, it naturally occurred to me that I should test the alkali solubility of other germs and proteins.

I found that the meningococcus was about as easily dissolved in alkali as the gonococcus, and that the influenza-bacillus of Pfeiffer was even more soluble. When the meningococcus was dissolved in alkali and the solution brought back to the neutral point it was found to act as a good antigen in the complement-fixation test for cerebro-spinal fever. A gonococcal antigen gave positive results with the serum of meningitic cases, and a meningococcal antigen gave weakly positive results with the serums of gonorrhœal subjects. These facts are sufficient to show the close relationship between the two germs. This finding was confirmed by A. S. G. Bell.[1]

Other germs, however, were found to be much less soluble in alkali than the gonococcus; the *Micrococcus catarrhalis*, for example, shows scarcely any evidence of solution in either N/10 or N/1 NaOH. N/1 represents 4·2 per cent. NaOH, but the *M. catarrhalis* required for its solution strengths as high as 15 to 20 per cent. NaOH. Organisms of the typhoid, dysentery, and *B. coli* group were found to dissolve fairly easily in alkali, but were not so soluble as the gonococcus. Gram-positive organisms were, as a rule, but not always, more difficult to dissolve in alkali than Gram-negative germs; the pneumococcus and streptococcus were, as a rule, more easily dissolved than the various staphylococci. The most difficult germ of all to dissolve was apparently the tubercle bacillus. Various animal tissues also showed marked differences in alkaline solubility. Leucocytes (pus cells) were more easily dissolved in alkali than epithelial cells, and brain and testicular tissue was apparently more difficult to dissolve than muscle. It was found that antiformin, which consists of 15 per cent. NaOH + 15 per cent. sodium hypochlorite, was a much more powerful solvent than NaOH alone. Germs like the gonococcus, pneumococcus, and steptococcus, as well as those of the typhoid, dysentery, and *B. coli* group, can be dissolved in antiformin in a few minutes. The tubercle bacillus, on the other hand, is much more resistant, requiring several hours. Although all germs, and apparently all proteins, were found to be more or less soluble in alkali, it was noticed that some, like the gonococcus, appeared to dissolve entirely; others, such as diphtheroids and the tubercle bacillus, dissolved only partially and left a considerable amount of undissolved material behind. In all cases, however, a considerable amount of protein went into solution in the alkali; and all these solutions behaved in the same manner, as indicated in the table under paragraph 5. All gave the protein colour tests. Meta-protein was always thrown out by the addition of acid, and the acid supernatant fluids always contained proteins resembling proteoses.

8. *Further Biochemical Components of Germs and Other Proteins—viz., Acid-Soluble, Alcohol-Soluble, and Chloroform-Soluble Fractions.*

The above researches apparently proved that the various germs and proteins examined each contained an alkali-soluble protein material. A further study was made with regard to the substances which remained insoluble in the alkali; the tubercle bacillus afforded the most striking example.

---

[*] The precipitate can be further detoxicated by alternate solution and precipitation repeated several times until the supernatant fluid no longer gives a precipitate with picric acid.

† The substance resembling primary proteose is precipitated with half saturation with ammonium sulphate and with 70 per cent. alcohol.

‡ The substance resembling deutero-proteose is precipitated with full saturation with ammonium sulphate and with absolute alcohol.

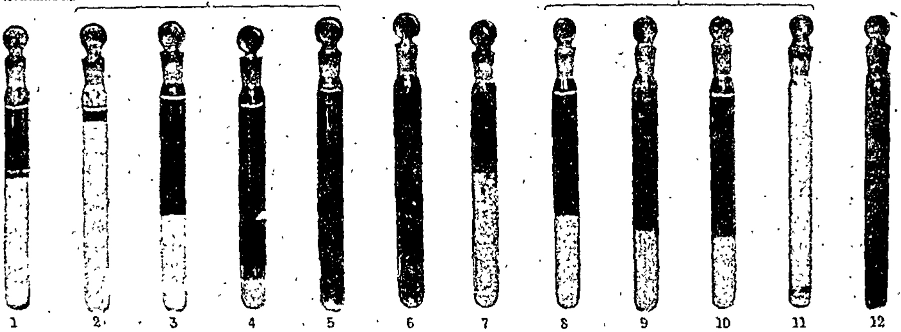
When a mass of solid tubercle bacilli is treated with twice its volume of antiformin and placed in the incubator for several hours it is apparent that a considerable part of the solid has gone into alkaline solution. The tube of the material, especially after centrifugalisation, separates more or less into three layers. In the bottom of the tube there is a heavy, insoluble substance, above this is a deep yellow fluid, and floating on the surface is a whitish, undissolved material of low specific gravity. The yellow fluid, which consists of the alkali-soluble protein of the tubercle bacillus, is separated from the insoluble parts by filtration through a fine paper. The insoluble substance is collected from the paper, placed in a tube, and treated with twice its volume of N/1 HCl. After standing for a few hours the acid mixture is also filtered through a fine paper.

The acid-soluble protein.—On examination of the acid filtrate it is found to give the protein colour tests. Moreover, when this acid filtrate is rendered definitely alkaline by the addition of N/1 NaOH, a white, flocculent precipitate is produced. When this precipitate is removed by centrifuging or filtration it is found that the supernatant alkaline fluid or filtrate contains proteoses which can be precipitated by addition of ammonium sulphate or alcohol.

QUANTITATIVE BIOCHEMICAL ANALYSES OF THE GONOCOCCUS (FIGS. 1–6) AND THE TUBERCLE BACILLUS (FIGS. 7–12).

Detoxicated Gonococcus Vaccine
(contains all of the non-toxic antigenic fractions shown below).

Detoxicated Tubercle Bacillus Vaccine
(contains all of the non-toxic antigenic fractions shown below).



1. Mass of gonococci, unchanged, toxic.
2. Gonococcus, meta-protein, alkali-soluble, non-toxic, antigenic.
3. Gonococcus, proteose, alkali-soluble, non-toxic, antigenic.
4. Gonococcus, protein, acid-soluble, non-toxic, antigenic.
5. Gonococcus, lipoid (?), alcohol-soluble, non-toxic, antigenic.
6. Gonococcus, endotoxin, toxic, not antigenic.

Note the relatively large amount of alkali-soluble protein present in the gonococcus, whereas the amount of alcohol-soluble substance (lipoid ?) is very small. The intracellular toxin in the right hand tube is in solution and its brown colour is not demonstrated in the photograph.

7. Mass of tubercle bacilli, unchanged, toxic.
8. T.B., meta-protein, alkali-soluble, non-toxic, antigenic.
9. T.B., proteose, alkali-soluble, non-toxic, antigenic.
10. T.B., protein, acid-soluble, non-toxic, antigenic.
11. T.B., lipoid (?), alcohol-soluble, non-toxic, antigenic.
12. Tubercle bacillus, endotoxin, toxic, not antigenic.

Note the large amount of alcohol-soluble substance (lipoid ?) present, which is light and tends to float to the top. The quantity of alkali-soluble protein is much less than in the case of the gonococcus. The intracellular toxin in the right hand tube is in solution in alcohol, and its brown colour is not demonstrated in the photograph.

Before proceeding further let us note that we have isolated from the tubercle bacillus the following components:—

(*a*) An alkali-soluble meta-protein which is precipitated with acid and whose acid supernatant fluid contains proteoses.

(*b*) An acid-soluble meta-protein which is precipitated with alkali and whose alkaline supernatant fluid also contains proteoses.

Now (*a*) behaves to an alkali as (*b*) behaves to an acid; conversely (*a*) behaves to an acid as (*b*) behaves to an alkali; so that as far as acids and alkalis are concerned, their action is diametrically opposite. Indeed, it would almost appear that protein (*a*) is negatively charged with hydroxyl-ions, and that protein (*b*) is positively charged with hydrogen-ions.

(*c*) *The alcohol-soluble substance.*—Returning again to our chemical analysis of the tubercle bacillus it is found after the alkali and acid soluble proteins (*a*) and (*b*) are dissolved therefrom that a residue still remains. This residue is now treated with three times its volume of absolute alcohol, and after standing for an hour the mixture is filtered. When we add to this alcoholic filtrate twice its volume of water a dense white cloud appears in the fluid. After standing for one or two days the fine colloid particles of this white cloud clump together into masses, which usually float towards the surface of the liquid. I take it that this white precipitate of low specific gravity, which is thrown out of alcoholic solution on the addition of water, is of the nature of a lipoid or lipo-protein. This lipoid alcohol-soluble substance is insoluble in acid and even in boiling NaOH. The lipoid precipitate when first formed is so fine that it will pass through a filter paper. After standing for two days, however, the particles, having clumped together, are easily removed by filtration from the alcohol-water medium.

(*d*) *The chloroform-soluble substance.*—After successive treatments with alkali, acid, and alcohol respectively, it is found that an appreciable quantity of the tubercle bacillus substance is still left undissolved; but this remnant appears to dissolve entirely in chloroform. This chloroform-soluble material may be precipitated by the addition of alcohol to the chloroform, and the precipitate may then be separated by filtration.

From the above analysis it is apparent that the tubercle bacillus can be split up into four main fractions or components.

(*a*) Alkali-soluble meta-protein + proteoses.
(*b*) Acid-soluble meta-protein + proteoses.
(*c*) Alcohol-soluble substance.
(*d*) Chloroform-soluble substance.

For successful splitting up of the tubercle bacillus, as well as of other germs and proteins, it is interesting to note that the above order of analysis must be maintained. For example, if we first treat the mass of tubercle bacilli with N/1 HCl or with alcohol at blood heat, practically nothing is dissolved away. It would almost seem that these four fractions of the germs are closely compounded and cannot readily be dissolved out separately until the compound has been broken up with alkali or antiformin.

9. *Content of Different Germs and Proteins: Same Types but Varying Proportions of Component Substances.*

Having definitely ascertained that the tubercle bacillus is made up of the four distinct components described above, one turned again to make a more careful analysis of the gonococcus. The gonococcus had at first appeared to consist almost entirely of alkali-soluble material, but careful analysis of a large mass of this germ, amounting to 20 c.cm. of solid wet substance, revealed that the organism also contained acid-soluble and alcohol-soluble fractions; no chloroform-soluble substance was detected. Large masses of many other species of germs and proteins were now treated in the same manner; it was found that all contained the fractions (*a*), (*b*), and (*c*), whilst some also contained the chloroform-soluble fraction (*d*).

In this series of analyses the interesting fact was revealed that each different germ and each different animal tissue contained the various components common to all in widely varying proportions. I have not sufficient space here to give the results of my whole series of analyses, but Table II. will suffice to demonstrate my contention.

It must be noted that the percentages given are very approximate, being estimated from the volume of wet precipitate obtained after centrifuging. Much more accurate results would be obtained by weighing the dried precipitates. In spite of the crudeness of my methods the results are striking. I am indeed convinced that by developing this method of technique we shall be able in the future to diagnose accurately the different species of tissues and of germs and even of the different strains, by pure biochemical analysis.

Even with the crude volumetric measurements which I have employed one can detect distinct differences in the biochemical composition of such closely allied organisms as *B. typhosus*, *paratyphosus A*, and *paratyphosus B.* I have already pointed out that some germs and tissues are very easily dissolved, even in weak alkali, whilst others are very difficult to dissolve and require strong solutions like antiformin. My analysis of many varieties of germs and tissues brought to light the interesting fact that this solubility depended upon the lipoid content of the germ or tissue. The less the amount of alcohol-soluble substance (lipoid) present the greater is the solubility in alkali, and vice versa. The influenza bacillus contains only the merest trace of lipoid, and is in consequence very soluble even in N/10 NaOH. The tubercle bacillus, on the other hand, contains some 32 per cent. of alcohol-soluble material, and on this account is very resistant to alkaline solution. It requires the action of antiformin for several hours. This fact is indeed so striking that one can prophesy a low lipoid content in a protein which dissolves readily in weak alkali; and conversely, when a protein disintegrates with difficulty it assuredly contains a high percentage of this alcohol-soluble material. (See Figures.)

TABLE II.—*Percentages of Content.*

Germs or proteins.	Tubercle bacillus.	Gonococcus.	Staphylococcus.	B. typhosus.	B. coli.	Ox heart.	Ox testicle.
Alkali-soluble substance	28	75	48	60	25	76	36
Acid-soluble substance	25	7	26	27	26	10	22
Total proteose	7	17	3	11	44	8	7
Alcohol-soluble substance... ...	32	1	23	2	5	5	34
Chloroform-soluble substance...	8	0	0	0	0	1	1

10. *Antigenic and Comparatively Non-toxic Nature of Protein Split Products Described Above.*

In the early part of my investigation I had ascertained that the alkali-soluble fraction of the gonococcus was antigenic, as estimated by the complement-fixation reaction and by the therapeutic results obtained when injected into gonorrhœal subjects. It was found, moreover, that this alkali-soluble fraction was very much less toxic than the actual germ itself. Further, the proteoses associated with the alkali-soluble fraction were also antigenic, and although they had a provocative power they were nevertheless comparatively non-toxic.

Similar experiments were now carried out with regard to the acid-soluble, alcohol-soluble, and chloroform-soluble fractions. It was found that the two former components gave good results when used as antigens in the complement-fixation test for gonorrhœa. Further inoculation experiments in human subjects showed that they were apparently no more toxic than the alkali-soluble component of the germ. These experiments were repeated with the component parts of the tubercle bacillus, with approximately the same results.

E. P. Pick[7] and other observers have inclined to the belief that the alcohol-soluble "waxy" substances from the tubercle bacillus and other germs were toxic and non-antigenic, but it would appear that this belief is erroneous. It is now well known that lipoid substances may be highly antigenic, one of the most notable examples being the alcoholic extract of heart employed in the Wassermann test. Lipoids, moreover, are not necessarily highly toxic, since the staphylococcus contains a large amount of alcohol-soluble substance, and yet is one of the least toxic of all germs. Pfeiffer's bacillus, on the other hand, is very highly toxic, yet it contains practically no lipoid or alcohol-soluble material.

OBSERVATIONS UPON A CASE OF
FILARIA (LOA) LOA INFECTION.

BY GEORGE C. LOW, M.A. ST. AND., M.D.,
C.M. EDIN., M.R.C.P. LOND.,
SENIOR PHYSICIAN, HOSPITAL FOR TROPICAL DISEASES, ENDSLEIGH GARDENS, N.W.; LECTURER AND CONSULTING PATHOLOGIST, LONDON SCHOOL OF TROPICAL MEDICINE;
AND
ELIZABETH J. O'DRISCOLL, M.B. N.U.I.,
D.P.H., D.T.M.,
HOUSE PHYSICIAN, HOSPITAL FOR TROPICAL DISEASES.

General Symptoms.

INFECTIONS with the nematode parasite *Filaria loa* (*Loa loa*), though often exhibiting few or no clinical symptoms of any definite importance, are nevertheless of great interest to the filariologist. Occasionally the adult parasites in their wanderings about the connective tissues pass under the conjunctiva on to the eye, and they have been removed from this position in many instances. Such an occurrence as a worm in the eye naturally makes a great impression on the layman, who does not forget it when he comes to detail his troubles to the doctor. Calabar swellings, swellings of a fugitive nature, about the size of a pigeon's egg or larger, are also met with; these come up suddenly, are painless, do not pit on pressure, and generally disappear in two or three days of their own accord. In rare cases[1] a generalised swelling of a part is met with or a pruritic condition may be seen, while in one case there was great pain in the eye with photophobia. We have recently seen a case where, instead of a small local swelling, there was a generalised swelling of the forearm of the nature of a solid œdema. This lasted for a considerable time and ultimately disappeared. When the adult worms are near the surface they often give rise to pricking sensations with itching, and the patients soon get to know these and can locate where the worm is quite accurately.

Pathogenesis of Calabar Swellings.

Students of the subject will remember that Sir Patrick Manson suggested[2] that the Calabar swelling might be produced by the adult female worm giving birth to a generation of embryos at that spot, and in one case he demonstrated embryos from such a swelling. The experiment was vitiated, however, by the fact that the patient had many embryos in the peripheral blood at the time; their presence in the films was no doubt due to the needle wounding blood-vessels on its way in. That such was so one of us (G. C. L.) was able to demonstrate recently in a case of *F. loa* infection where there were no embryos in the peripheral blood. In this instance, though the Calabar swelling—which was a perfectly typical one—was punctured in many directions, no embryos could be detected in the juice aspirated.

There is no doubt that these swellings are caused in some way or other by the worms; they are probably due to the excretion of a toxin into the tissues, a possibility rendered still more likely in such cases by the fact of the presence of a well-marked eosinophilia as well. This eosinophilia is a very constant feature, the numbers varying between 12 and 20 per cent. as an average. In the absence of other causes one has been able to diagnose loa infections correctly by this feature alone.

Diagnosis.

Four distinct points will help one, then, in diagnosing *F. loa* infection: (1) the actual presence of the adult worm or worms, have any been extracted from or definitely seen in the eye? (2) the presence of *F. loa* embryos in the peripheral blood—they are easily differentiated from *F. bancrofti* embryos by anyone who has studied the subject closely; (3) the presence or definite history of Calabar swellings; and (4) eosinophilia in people from the endemic area, with nothing else to explain its presence.

---

[1] Low, G. C.: Jour. of Trop. Med. and Hyg., Jan. 2nd, 1911.
[2] Trans. Soc. of Trop. Med. and Hyg., vol. iii., No. 5.

One or more of those cardinal symptoms may be present in any individual case. Embryos are often absent from the peripheral blood; this absence, often of a prolonged nature, is difficult to explain. Those interested may consult the paper on this subject already mentioned.[1]

History of the Case.

B., male, aged 28. Admitted to Hospital for Tropical Diseases Jan. 21st, 1921. Born in Scotland; went abroad to Southern Nigeria 1914; Cameroons 1916; came home to U.K. December, 1920, this being his fourth leave home.

Previous illnesses.—Suffered a good deal from malaria; gastritis in 1918; diarrhœa once; no definite clinical dysentery.

Present illness.—Went to doctor for fever in Nigeria November, 1920; an examination of the blood for malaria showed the presence of diurnal filarial embryos, as well as malarial parasites. On arrival in England as fever was still troubling the patient; he came into the Hospital for Tropical Diseases to have it treated.

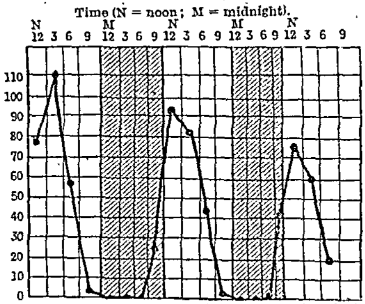
Examination.—Temp. raised; spleen enlarged. These symptoms quickly disappeared on proper doses of quinine being administered, and, of course, had nothing to do with the filarial infection.

Filarial history.—No definite Calabar swellings; (?) perhaps one. Knocked his right forearm one day; on the same day his right hand became swollen, remaining so for two days, after which it went down of its own accord. No history of worm ever being seen in eye.

Blood examination.—Many *F. loa* embryos present in day blood; none in night blood. Also a few *F. perstans*. No malarial parasites found.

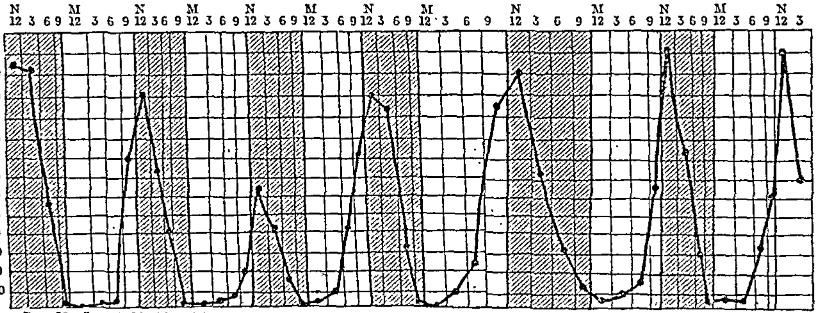
CHART 1.

In each of the Charts the shaded portions represent the time during which the patient slept. The figures at the side are the numbers of *F. loa* embryos in 20 c.mm. of blood.



CASE M.—Ordinary habits of life. Showing diurnal periodicity of *F. loa* embryos.

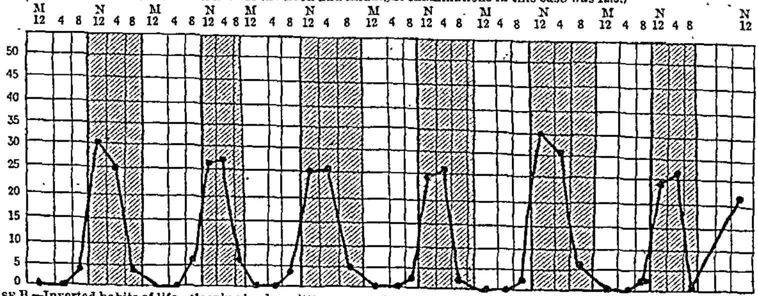
CHART 2.



CASE M.—Inverted habits of life—sleeping by day, sitting up and working at night. No change or inversion of periodicity.

CHART 3 (Case B).

(The actual time of the noon and midnight examinations in this case was 12.5.)



CASE B.—Inverted habits of life—sleeping by day, sitting up and keeping awake all night. No change or inversion of periodicity.

Count of corpuscles.—R., 4,108,000. W., 8800. Hb. 90 per cent. Differential: P.M.N., 45 per cent.; L.M., 6 per cent.; L., 31 per cent.; E., 18 per cent. = 100. Slight anæmia then, due, no doubt, to the malarial element in the case. Well-marked eosinophilia.

Stool examinations.—No ova of any helminths present. No protozoa.

Urinary examinations.—Nothing abnormal, no albumin, blood, or sugar.

Subsequent history.—The routine blood examinations will be seen on the charts.

In March a typical Calabar swelling developed on the right wrist, thus it will be seen that the patient had eventually three of the cardinal signs of the infection—viz., the Calabar swelling, the day embryos of *F. loa*, and the eosinophilia.

Experiments upon the Periodicity.

Filarial periodicity has never been satisfactorily explained, though many theories have been put forward from time to time. The term has been applied to the presence in the blood of the embryos of *F. bancrofti* by night and their absence by day, or conversely, in the case of *F. loa*, to their absence by night and their presence by day. Chart 1 shows the diurnal periodicity of *F. loa* very well. The maximum number of embryos are in the blood about midday or a little later and quite absent from the blood at night. This regular habit goes on day by day without much variation. One of the suggested explanations of periodicity is that it is due to the habits of the intermediate host, this being nocturnal in the case of *F. bancrofti*, diurnal in the case of *F. loa*. This, however, will not explain the non-periodicity of most of the other filaria, such as *Dirofilaria immitis* of the dog, whose intermediate host is nocturnal, *F. perstans*, and *F. demarquayi*; nor does it completely explain the non-periodicity of the South Sea variety of *F. bancrofti*. The possibility of the latter being a different species, or at least a distinct sub-species, still remains. If not that, at any rate it is a very well marked variety, differing from the common *F. bancrofti* in other respects (pathologically) as well as in its irregular periodicity.

Inversion of Periodicity.

Stephen Mackenzie first showed that it is possible to change the periodicity of *F. bancrofti* by changing the habits of the patient—e.g., by making him sit up all night and sleep all day. If this is done the periodicity changes right round, the embryos now appearing in the peripheral blood by day and not by night.

Many years ago now (1904) one of us (G. C. L.) had the opportunity of trying a similar experiment on a case of *F. loa* infection, under the care of Sir Patrick Manson at the Albert Dock Hospital. Though the protocols and details of this work have never been published, mention of the bare fact that the experiment was unsuccessful has appeared from time to time in the different editions of Sir Patrick Manson's book on Tropical Diseases. I have had the opportunity of verifying those facts again, in the case at present under discussion, and have found that they harmonise completely with those obtained in 1904; it may therefore not be out of place to publish them together now. For convenience the results have been put in the forms of charts (Charts 2 and 3) and a perusal of those will show that though the habits of the patient were completely inverted no corresponding change in the periodicity of the embryos took place, this being in direct opposition to similar experiments on *F. bancrofti*, as just mentioned above. In both cases the patients went to bed at 9 A.M. and stayed there till 9 P.M. At the latter hour they got up and sat up all night, reading or doing some work about the wards. Both slept well during the day. Measured quantities of blood as first recommended and practised by one of us in 1903[3] were always taken, the standard quantity of 20 c.mm. being adopted.

Attempts to Eradicate the Infection by Antimony.

A series of antimonium tartaratum injections were given intravenously to determine if they would have any effect on eradicating the infection. They failed entirely, just as they have done in a series of cases of *F. bancrofti*, treated in a similar manner by ourselves.[4] A table of the examinations made and the amount of antimony injected has been constructed similar to those on our *bancrofti* cases, and a glance at it gives all the details necessary. There might be a slight diminution of the numbers of embryos towards the end of the course, but even this is not certain. A total of 25 gr. of antimonium tartaratum in all was given, the injections having no bad effects upon the patient.

In addition to the *F. loa* infection there was also a scanty infection of *F. perstans*, not sufficient, however, to do any accurate counts upon. These were not destroyed by the antimony either, an interesting observation, as this embryo is non-sheathed, and some have suggested that it is the sheath of the *bancrofti* and *loa* embryo that protects them. As regards eradication of the infection, of course, this is not the point: it is no use destroying the embryos, even if we could, so long as the adults are not destroyed, as the latter cause the symptoms, and if still alive will go on pouring embryos into the blood stream. The embryos are just an index or means of determining what effect, any, the drug used is having on the adult worms. henever those are destroyed, as by an attack of phangitis in *F. bancrofti* infections, then the embryos quickly disappear from the blood and do not return.

Table Showing Examinations made and Amount of Antimony Injected (Case B).

A = number of *F. loa* embryos in 20 c.mm. of blood.
B = number of grains of tartar emetic injected, these being given in the afternoons between 4 and 5 P.M.
The examinations were made at 12 noon on every occasion.

J. B. Christopherson has recently again raised the question of the non-toxicity of large doses of antimony in different tropical affections in which this drug is used. We agree with him that, with ordinary care, there is little or no danger in giving such injections, and that if necessary large amounts may be given, as in our own series of cases of bilharzia.[5] In cases of kala-azar and ulcerating granuloma quantities up to 53½ gr., 64¾ gr., and even 114 gr. have been administered by us. In most of the tropical diseases now being treated with antimonium tartaratum such large amounts will not be found necessary, 30 to 40 gr. probably being the maxima required. The methods of giving the drug and the slight toxic symptoms which may follow its administration are now so well known that it is quite unnecessary to reiterate them here. These details may be studied in the paper referred to above and in the different publications of Christopherson and others.

SPINAL ANÆSTHESIA FOR SUPRAPUBIC PROSTATECTOMY.

By H. M. PAGE, F.R.C.S. ENG.,
ANÆSTHETIST TO THE WEST LONDON HOSPITAL.

A FORMER report on this subject was published in THE LANCET of May 15th, 1915. Since then, owing to the kindness of Mr. John Pardoe and Mr. Sydney MacDonald, I have greatly increased my experience in the use of this method of anæsthetising for suprapubic prostatectomy, with the result that though I still use it for choice in almost every case I have modified my technique in some particulars.

I now use a 10 per cent. solution of stovaine (Billon's) without the addition of glucose. I have gradually cut down the dose of stovaine to a maximum of 0·03 of a gramme (three-tenths of a cubic centimetre of a 10 per cent. solution). In some cases, on account of great age, a much broken-down constitution, or comparatively low blood pressure, I have used a dose of 0·025 of a gramme of stovaine successfully. The patient is always operated on with the table slightly inclined, head downwards, and this position should be retained for carrying the patient back to bed, and when in bed until all effects of the spinal injection have passed off. The foot of the bed should be raised high enough to make a more decided slope than that of the operating-table. The Trendelenburg position can of course be used if desired. In every case I produce unconsciousness, never surgical anæsthesia, by administering some general anæsthetic in combination with oxygen.

---

[3] Filaria Perstans, Brit. Med. Jour., March 25th, 1905.

[4] THE LANCET, 1920, ii., 551, and 1921, i., 221.

[5] Low, G. C., and Newham, H. B. G.: THE LANCET, 1919, ii., 633.

According to the condition of the patient, I have used nitrous oxide and oxygen and ether, A.C.E. and oxygen followed by ether and oxygen, or ether and oxygen alone. A subcutaneous injection of morphia and atropine, of a dosage suitable to the age and condition of the patient, is given half an hour before the operation.

I still inject in the second lumbar space, with the patient lying on his side. I withdraw very little more spinal fluid than the quantity of solution I am going to inject. My experience in the use of spinal anæsthesia for these cases and for a great number of operations in general surgery has made me think that the best way to avoid after-headache is to withdraw little spinal fluid, use as fresh a solution of stovaine as possible, and avoid collapse by position maintained until the effect of the spinal injection has completely passed off.

In the preparation of the patient I avoid starvation as much as possible, and he should be allowed to drink water up to the time of operation. It is a great advantage to the patient to continue to drink water up to the time of the administration of an anæsthetic for every kind of operation, provided there is no obstruction in the alimentary tract. Dehydration is prevented, the stomach is washed clean, and the risk of post-anæsthetic vomiting is diminished.

Results from the Modified Technique.

With the use of the above technique I have had no trouble or anxiety during the operation. In every case there has been good relaxation of the abdominal muscles. There has been no stovaine collapse and no increased tendency to recurrent hæmorrhage. Headache has been extremely rare and negligible. As the general anæsthesia is not carried to the surgical degree and is of very short duration, the patient recovers from it with extreme rapidity, even if a chloroform mixture or ether has been used, and soon takes drink and food. There has been no post-anæsthetic vomiting. In every case the patient has left the table in an exceedingly good general condition. There has been no case of immediate death, and the operative mortality, including the cases in my first report, has been under 5 per cent. The list of cases contains a large percentage of the aged, two over 90 years old, and a full proportion of patients with broken-down constitutions. I have not yet found it necessary to use spinal anæsthesia for a preliminary cystotomy.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF

ACUTE APLASTIC ANÆMIA.

BY F. E. LARKINS, M.D.

ATTENTION has recently been directed to the risks arising from exposure to gamma rays, and the following case is reported to sound a note of warning.

A. B., aged 43, had been working at radiography for 15 to 18 years. He was of excellent physique, and for the past 18 months had been putting on weight; his general health had never been better. His complexion was always sallow, a fact which, unfortunately, masked the onset of the fatal anæmia.

In October, 1920, a blood count was taken, one might say quite accidentally, as far as the present illness was concerned, but which, in view of subsequent events, turned out to be of great interest. The result then was:—

Blood count: Reds, 4,200,000; whites, 7200; Hb, 85 per cent.

Differential leucocyte count[*]: L., 38 per cent.; P., 60 per cent.; E., 1·7 per cent.

This suggests that at that time disease had already actually begun—that is, five months before its termination and three months before any symptoms were complained of.

In January the patient's colour was noticeably changing from his normal sallow to a peculiar lemonish tinge. He then began to complain of shortness of breath and loss of appetite. He still kept on working at high pressure, and refused to consult anyone. On Feb. 4th, however, he gave in. At this stage he was well nourished and of powerful physique. His temperature was 100·6° F. at night, pulse 90, and he now said he thinks he had been running a night temperature for a month past. This temperature came on regularly every afternoon at about 4 o'clock, and increased to 10 P.M. with intense backache. His blood pressure was 110. Slight dilatation of heart with hæmic murmur at the apex. He had a troublesome cough, and a few moist sounds were found at both bases.

Blood count: reds, 2,700,000; whites, 1600; Hb, 54 per cent.

Differential count: L., 76 per cent.; P., 20 per cent.; E., 3 per cent.

Thus showing a serious drop in both red and white corpuscles and complete inversion of the ordinary percentage relation of lymphocytes to polymorphonuclears. No poikilocytosis, no nucleated reds, no variation in the size of the red cells were to be seen. Urine showed nothing.

He was put to bed, given arsenic by mouth, and daily injections of cacodylate of iron and strychnine, and salicin 10 gr. every day to control the intolerable backache he got every evening with the temperature. During this first week he appeared to improve. His temperature came down, his appetite got better, and he seemed stronger.

Owing to the possibility of an infective endocarditis I had his heart examined by Dr. Strickland Goodall, who came to the conclusion that there was none present, but that it was purely a hæmic heart. Bacteriological examination of the blood on two separate occasions gave a negative result. Septic foci were sought for from every conceivable source, but none were found anywhere excepting for one septic tooth which was extracted.

At this stage he appeared so much improved that I let him go to the country to pick up. In a week he had to come back, as his temperature had run up to 103° at night and he was evidently much worse.

On Feb. 21st his red cells had dropped to 2,850,000 and hæmoglobin to 45 per cent. His urine now showed a trace of albumin with a few blood discs. The fæces were examined for blood but none found. His nose began to bleed, slightly oozing in the night; severe headache complained of; chest clear; pulse 88–90; temperature, 100°–101°.

On March 1st cerebral symptoms began to be noticed in some loss of memory and clearness, which previously had always been acute. On the 6th blood count still showed a steady rapid fall.

Blood count: Reds, 1,350,000; whites, 1030; Hb, 26 per cent.

Differential leucocyte count: P., 20 per cent.; L., (large) 72 per cent., (small) 6·5 per cent.; E., 5 per cent.; B., nil; H., 1 per cent.

Macrocytes and microcytes present; poikilocytosis present; no nucleated reds.

March 9th: Complained of blurring of vision in right eye.

10th: Ditto in left eye. Examination showed extensive retinal hæmorrhages in both eyes. Temperature still ran between 100°–101° every evening, with morning drop to normal. Pulse steadily rose to 90–100.

It was now decided to resort to transfusion of blood. Patient's blood was tested for agglutination and was found to be of group 4, and a group 4 donor was procured.

16th: Mr. Norman Lake transfused 9½ oz. of blood. This was followed by a very severe rigor and intense general discomfort. Temperature rose to 106·2°; pulse to 150.

17th: He felt and looked somewhat better and the temperature dropped to 99·2°. Nose began to bleed slightly.

18th: Nose oozed continuously and nothing could stop it. The temperature rose again to between 101°–103° and pulse about 120. The headache, which previously had been troublesome, left him. He still took his food very reasonably well and was constantly sleeping.

19th: Blood count was again taken. It will be seen that a very noticeable change had taken place in the differential count.

Blood count: Reds, 1,005,000; whites, 840; Hb, 18 per cent.

Differential count: P., 41 per cent.; L., (large) 54 per cent., (small) 4 per cent.; E., nil; B., nil; H., 1 per cent.

Poikilocytosis present; macrocytes and microcytes present.

21st: The heart got rapidly weaker and the patient died.

Commentary.

The rapid diminution in the red and white corpuscles was very noticeable in this case, the reds disappearing at the rate of roughly 250,000 a week. The colour index was never over 0·9. The differential leucocyte count was remarkable, especially as it corresponds exactly to Dr. A. E. H. Pinch's two cases of a similar nature, that have been, or are just about to be, reported, due to the effect of radium, and which ran an almost identical course.

There seems no other possible cause for the onset of this case other than X rays, and the interesting thing about this is that this radiographer had recently changed over from the soft tubes to the hard tubes for the greater part of his work. So the warning to be got from this case is that the protection hitherto employed in the use of harder tubes is not efficient. Further, it would appear advisable for radiographers and all those who are employed in radiographic work or with radium to have their blood examined periodically—say every six months—as by so doing the disease could be recognised at a very early stage, and probably be stopped.

In this case the transfusion did not appear to help in arresting the progress of the disease in any way, but I understand that in children with aplastic anæmia not due to X rays or radium it has been employed [illegible] excellent results.

A NOTE ON

A SMALL OUTBREAK OF DYSENTERY IN A PROVINCIAL TOWN.

By J. S. MANSON, M.D. EDIN., D.P.H.,
MEDICAL OFFICER OF HEALTH, RUNCORN RURAL DISTRICT;
AND
H. A. MITCHELL, B.A., M.B. TORONTO,
BACTERIOLOGIST, RESEARCH LABORATORIES, RUNCORN.

CASES of dysentery in England at the present time are of some importance in view of its importation by large numbers of men who have been in the Eastern theatres of war. Following is a brief description of a recent small outbreak in the town of Warrington with the bacteriological findings.

One of us (J. S. M.) was called on Sept. 6th, 1920, to see a girl, aged 5 years, who was suffering from tenesmus and frequent stools, largely, and at times wholly, composed of blood and mucus. On the 15th her brother, aged 9 months, took ill with the same complaint, but in a more severe form. He had about 20 motions per diem, frequently passing only pure blood. Temperature ranged from 101° to 103° F.; the child died on the 23rd.

On the 22nd in the next house but one in the same row a child (I. K.), aged 6 years, was attacked; and in succession the following children in the same family fell ill; on the 28th, her brother (H. K.), aged 10 years; on the 30th (L. K.), aged 11; on Oct. 2nd (E. K.), aged 8. I. K., H. K., L. K., were all seriously ill with tenesmus, frequent stools, 18-20 per diem, with passage of blood and mucus; after the end of a week from the onset of the illness, only shreds of tissue were seen in the stools. E. K. had the disease in a milder form; the stools, although containing blood and mucus, only numbered 8-10 per diem. There was another child who was only ill for a day with one attack of diarrhœa. The mother and father were not attacked.

On Oct. 3rd two adult females, the occupants of the house at the end of the row, 30 yards distant from the heavily infected house, were attacked with severe diarrhœa. The clinical features in all except the two last mentioned were those of true dysentery—tenesmus, frequent passage of blood and mucus in stools, which at the end of a week changed to tissue shreds, tenderness over splenic flexure and descending colon, flushed face, furred tongue, and temperature from 101° to 102°. There was no vomiting.

Treatment consisted in withholding milk and giving beef-tea, thin arrowroot gruel, thin, well-strained pea-soup, and egg-albumin water. Bismuth carbonate, catechu, and 2 minim doses of liq. opii sedativus every four hours. On Oct. 16th all were convalescent, with only one or two normal stools per diem.

A stool from the boy (H. K.) containing only tissue shreds was sent to one of us (H. A. M.) for bacteriological investigation with the following result:—

Fæces from H. K. showed the presence of a few squamous epithelial cells, probably of extraneous origin, and a considerable amount of mucus, connective tissue, but no blood. Cultural examination revealed the presence of two organisms, one the *Bacillus coli*, the other belonging to the dysentery group. This latter organism was a Gram-negative bacillus, non-motile, giving a fine glistening growth on potato, and a very slight turbidity in broth. It produced no gas, but gave an acid reaction in the presence of the following sugars—viz., glucose, galactose, lævulose, and to a lesser degree in maltose and mannite. From this will be seen a close relation to the Y-type as described by Harris, Gay, and Woolstein[1 2 3].

The serum from two of the cases—viz., L. K. and I. K.—showed very strong agglutinative powers for this organism, and two others—H. K. and E. K.—also agglutinated it, but to a lesser degree.

Injected into guinea-pigs it killed in nine days, and post-mortem examination of one of these revealed a large subcutaneous abscess at site of inoculation, and another in the liver. There was also marked congestion of the intestine. The organism was obtained in pure culture from both abscesses. These results point to a *Bacillus dysenteriæ* closely related to the Y-type. (It might be observed that the organism responsible for ulcerative colitis, summer diarrhœa, and asylums dysentery, all fairly common in England, is not of this type but of the Shiga-Kruse type.[4])

The bacteriological examination thus confirms the clinical diagnosis, and it is interesting that the outbreak should be so localised. No source of infection could be traced; inquiry as to the presence of a discharged soldier or other person from an infected area proved negative. Railway stables across the street were investigated as to the presence of horses from abroad. Only one horse there had been to France. A sample of dung was examined for the organism and proved negative. The sanitary system is one of pail closets, and at the time of the outbreak the weather was warm—in fact, the warmest period of the summer—and flies were numerous. The clinical history shows that the virulence soon died out and that children were the chief sufferers.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

CLINICAL SECTION.

REPORTS AND EXHIBITION OF CLINICAL CASES.

A MEETING of this section of the Royal Society of Medicine was held on April 8th, Sir ANTHONY BOWLBY, the President, being in the chair.

Dr. IVOR J. DAVIES reported two cases of

Hair-cast of the Stomach,

together with an abstract of 108 cases.

CASE 1 was that of a woman, aged 34, who had always enjoyed good health until six months before admission to hospital. At that time her legs became swollen and shortly afterwards the abdomen swelled and gradually increased in size. She was breathless and complained of palpitation on exertion. Indigestion had been present for some years and now took the form of pain and vomiting after meals, with slight hæmatemesis on a few occasions. A few days before admission the arms swelled. There had been headache and sleeplessness and for eight months amenorrhœa. The urine had diminished and was passed with a little difficulty. There was a tendency to diarrhœa. The case was first regarded as an unusual form of pregnancy. In the out-patient department there was seen to be a moderate degree of œdema of the limbs. The abdomen was distended and found to be occupied by a large mass extending from the left hypochondrium, across and below the umbilical region, upwards to the right costal margin. It was crescentic in shape, with a sharp depression on its upper surface. The outline was definite, the surface hard, smooth, and free from tenderness. The mass was freely movable in all directions. The normal splenic dullness merged with that of the mass. The urine was normal. The case was admitted with a tentative diagnosis of splenic anæmia, but in the ward the idea of pregnancy was revived, since external ballottement was obtained and hard parts could be felt per abdomen, which were firm and rounded, were all connected, and could be moved freely, apparently in a fluid sac. Various other diagnoses were made. The vomiting increased.

At an operation by Mr. Cornelius Griffiths the stomach was found to be enormously dilated and filled by a compact mass of hair which formed a perfect cast of the stomach and pylorus. The weight of the hair-ball was 6½ lb.; its length along the greater curvature 24½ in., and its greatest circumference 12½ inches. The hairs varied from 6 to 12 inches long, and were dark and like those of the patient. The mass was thickly covered by a slimy foul mucus, together with flakes of sebaceous or adipocere material. The stomach wall was hypertrophied, and its mucous membrane inflamed in places; there were also areas like those of leukoplakia. An hour after the operation the patient died.

CASE 2 was that of a woman, aged 33, who had noticed an increasing lump on the right side of the abdomen for three years. For two years she had suffered at intervals from vomiting in the morning, but never after meals. Occasional slight pain was felt over the swelling. She was a healthy-looking, well-nourished woman. On abdominal examination a hard, smooth, rounded, movable, painless lump was found in the right lumbar region, but did not appear to fill the loin. There was dullness distinct from the liver dullness. At an operation by Mr. A. W. Sheen a hair-cast of the stomach, with a prolongation into the pylorus and duodenum, was removed. The stomach wall was hypertrophied. The mass was 21½ inches long and 11 inches in its greatest circumference, the appendage withdrawn from the pylorus being 7 inches in length. It weighed 3½ lb. A few adherent strands of cotton were seen on its surface, also a hook similar to one shown in the interior on subsequent X ray examination. There were a large papilloma in the lesser curvature and several smaller ones over the antrum pylori. These were removed. The patient made a full and speedy recovery, and was discharged 14 days later.

After referring to the radiographic appearances of the disorder, during which he exhibited some radiograms taken by Mr. Thurstan Holland of two cases which he described in detail, Dr. Davies dealt with the diagnosis. This was mainly one of differentiation between malignant disease and hair-mass. The early age, sex, long history, good health, and the particular features of the tumour were significant, and if radiographic methods were used there should be no difficulty in the diagnosis. The mobility of the stomach with the enclosed mass and of the latter within the stomach, as made out by radioscopic palpation (Barclay and Ramsbottom) during fluoroscopic examination, were characteristic. History of hair-eating was seldom obtained, probably because the habit was, for the most part, unconscious. Small masses of hair might be passed per rectum, and lavage of the stomach might bring up a few strands of hair. According to Hausmann the presence of fatty acid plates and needles in the contents of the fasting stomach provided an additional feature. Butterworth in 1909 had collected 42 cases, Moore in 1914 53 cases, Ledra-Heazlit in 1914 70 cases, Matas in the same year brought the number of cases to 77, and the present paper concerned 108 cases.

Dr. B. T. PARSONS-SMITH showed a case of

Congenital Aortic Atresia.

The patient was a man aged 24. The symptoms were shortness of breath, even with slight exertion, pain in the left side of the chest, forcible beating of the heart, lack of ability for effort of any kind, frequent headache, giddiness, fainting sensations, general weakness of muscular power with excitement, and a functional incapacity of the lower limbs, particularly noticeable after resting. In March, 1915, the patient came up for military service, but general physical incapacity, which became manifest at the beginning of training, rapidly increased, and he was invalided four months later. In March, 1916, he again entered the army and in spite of recurrent disabilities remained at full duty for the greater part of the time until he was invalided in October, 1917. He was a pale-faced man of delicate appearance and his muscular development and general physique were distinctly below the average. The heart was enlarged, its rhythm regular, and the sounds clear. The second aortic sound was accentuated, the first sound at the apex was reduplicated, and a systolic murmur was audible in this region. The vessels were slightly thickened. Blood pressure readings were: systolic, 144 mm.; diastolic, 100 mm. Hg. There was no venous engorgement, no enlargement of the spleen, no clubbing of fingers, no cyanosis. Pulsation was exaggerated in the suprasternal notch and in the carotid and subclavian arteries, and there was a definite discrepancy in the pulses of the upper and lower extremities, those of the latter being diminished in size. Several thick-walled and tortuous vessels in the scapular region presumably indicated an anastomotic circulation between the arterial channels above and below the seat of the aortic occlusion. Electrocardiograms showed a bifid P wave in lead 2, a T wave whose ascending limb was unusually steep in lead 2, a slight increase in the length of the P-R interval which varied from 0·18 to 0·2 sec., and a bifid R wave in lead 3, the height of the second limb of the wave being conspicuously greater than that of the first. X ray examination confirmed the cardiac enlargement and showed a narrow aortic shadow extending to an abnormally high level.

The diagnosis was held to be congenital aortic atresia of adult type in which it might be inferred that the seat of the occlusion was situated below but in the vicinity of the entrance of the ductus arteriosus.

? Neoplasm of the Lung: Post-Mortem Findings.

Dr. M. CASSIDY reported the post-mortem findings of his case of ? Neoplasm of the Lung which was shown at a previous meeting of the section.[1]

The patient remained in good health till the end of January, 1921. During the first fortnight of February he had several slight hæmoptyses, and on the 16th he was readmitted suffering from great dyspnœa and stridor. He died two days later, having been at work up to four days before his death. A post-mortem examination, performed by Dr. E. Wordley, revealed a firm white growth which appeared to originate in the root of the left lung and had invaded the greater part of the lower lobe; the upper lobe, though free from growth, was completely collapsed, accounting for the upward and outward displacement of the apex beat observed clinically. The mediastinal glands were normal, and no other deposits could be found elsewhere. Histologically the appearances were those of endothelioma, though owing to much post-mortem autolysis an absolutely positive conclusion as to the nature of the growth was not possible.

Mr. C. W. G. BRYAN showed a case of Osteitis Fibrosa treated by resection of four inches of the humerus and insertion of boiled beef-bone graft.

Mr. G. MASSIE showed a case of

? Fibrocystic Disease of the Skull

in a girl, aged 21, who complained of inability to see properly from her right eye owing to increasing depression of the right eyelid. She said that she had had a swelling of that side of the head ever since she could remember, but that during the previous three weeks a smaller swelling had appeared, which she thought was softer. She also complained of headaches. The Wassermann reaction was negative; nothing abnormal was found on physical examination; the urine was normal and there was no family history of syphilis. The smaller and softer swelling for which she had sought treatment had almost disappeared, the main mass of the swelling was about the same size, but a smaller lump had appeared in the middle of the forehead. She was unwilling to have an operation. Mr. Magnus Redding reported that the radiograms showed diffuse absorption of bone and overgrowth of imperfectly defined new cancellous bone (? osteoid tissue) affecting the right frontal bone. Both horizontal and vertical plates were affected. Osteitis fibrosa was suggested. There was a single small cystic cavity above the internal condyle of the right femur. Otherwise the lower limbs, pelvis, and spine showed no abnormality. The left frontal sinus was very much enlarged.

Dr. S. A. K. WILSON said that he had seen three cases resembling this one which had proved to be endothelioma of the bone, and in two of the three the endotheliomatous growth had extended inwards to the cortex as well as outwards. He asked whether there was any evidence of intracranial lesion in this case. He suggested operation. Two of the three cases he had seen had been operated upon by Sir Victor Horsley.—Mr. MAGNUS REDDING said that he would like to see the case in a year to see if there was any alteration. Osteitis fibrosa in other bones gave rise to appearances similar to those in this case.—Mr. MASSIE, in reply, said that the neurological examination revealed nothing abnormal.

Mr. PHILIP TURNER showed a case of

Cystic Tumour of the Left Cheek.

The patient was a man aged 45. The swelling had been present for about five years and was about the size of a walnut. The man stated that he went to bed one night and found it next morning. Since then the tumour had persisted and had not altered in size. Removal of a carious tooth while in the army had not affected it. The tumour appeared to be a cyst in the substance of the cheek and not adherent to the skin or mucous membrane, and though related to the superior maxilla, the inferior maxilla and the malar bone, not attached to these structures. X ray examination showed nothing abnormal. The tumour was in front of the parotid gland, which was not enlarged and did not swell during meals; saliva was normally excreted, Stenson's duct not obstructed, and the cyst could not be emptied by pressure. It had been suggested that the tumour was a lipoma or a dermoid cyst, but its sudden appearance was not in keeping with either of these views. On retraction of the cheek from the alveolar process of the upper jaw a small patch of mucous membrane showing a number of dilated vessels could be seen, an indication of an old nævus which had atrophied. He suggested that the cyst might have developed in a nævus and been due to a hæmorrhage.

Mr. W. H. OGILVIE showed a case of

Parovarian Cyst

in a baby of 3 months who had been ailing since birth and treated for marasmus and cough.

She was admitted into the hospital in the middle of December, 1920, with cough and dyspnœa, and bronchopneumonia developed. Early in January a lump was noticed in the abdomen. The abdomen was distended and tympanitic. In the left lower quadrant was a large globular elastic swelling, dull to percussion, and giving the sensation of fluid. It was only slightly movable and its lower border could be felt per rectum. The temperature was 103° F., the pulse over 180 and very feeble, respirations 60. There were patches of solid lung at both bases. An ovarian tumour was suspected owing to the presence of two abnormalities of congenital type: a large rugose vulva like a cleft scrotum and a partial stricture at the recto-anal junction. The preceding child had been born with a hare-lip. However, the fixity of the mass and the distension of the intestine led to the diagnosis of an inflammatory exudate, shut off between coils of intestine. Under chloroform anæsthesia the mass was felt to be spherical, and was displaced by manipulation from the hypogastric to the umbilical region, where it lay slightly to the right of the mid line. A right paramedian incision was therefore made, whereupon greatly distended coils of gut presented, and free serous fluid was found in the peritoneal cavity. A globular swelling about 4 in. in diameter was exposed. As it could not be delivered it was punctured a trocar and about 12 oz. of golden yellow fluid
The flaccid cyst was then drawn out, its narrow clamped, divided, and tied off, and the abdomen
The pedicle sprang from the right side of the

---

[1] THE LANCET, 1920, ii., 1305.

operation took 15 minutes, and the child made a slow recovery.

Dr. G. W. Nicholson reported that the cyst wall was denuded of epithelium, but as there was a well-developed parovarian in its walls there could be no doubt that it was a parovarian cyst. No ovarian tissue could be found. The fluid, according to Dr. J. H. Ryffel, was rich in protein and contained no mucin. There were some red blood cells and white cells, mainly polymorphs. Methæmoglobin was present and a little bile pigment or hæmatoidin.

The chief interest lay in the rarity of the case. Ovarian tumours were not common in childhood, and the majority of those which had been reported had been in children between the ages of 7 and 15, while the solid growths, either dermoids or sarcomata, outnumbered the cysts by about 3 to 1. Only 7 cases of ovarian cyst occurring in the first year of life were on record, and of these 5 were post-mortem reports. Successful ovariotomies were published by Sant Anna of Brazil in 1896 and by D'Arcy Power in 1898. Parovarian cysts were still more uncommon, and no case had previously been reported in a baby. It was hard to see how so large a cyst could have become impacted in so small an abdomen. There was no twisting of the pedicle, but the cyst wall showed at one place a well-defined area of pressure necrosis. He attached importance to the closure of the abdominal wall by mass sutures. Every minute saved in a laparotomy of a baby was of importance, while the delicate tissues had little power to deal with buried sutures even when of an absorbable nature.

Mr. OGILVIE also showed a case of

Multiple Brodie's Abscesses in the Scapula.

The patient, a boy now aged 17, was admitted into an infirmary in July, 1917, with subacute osteomyelitis of one week's duration, affecting the right femur and right tibia. Pain in the right shoulder was followed later by swelling, and the joint was drained for a purulent synovitis. No sequestrum was found and he recovered full range of movement. In March, 1921, he was admitted to hospital with pain in the right shoulder and a swelling in the right supraspinous fossa. A skiagram taken by Mr. Magnus Redding showed three cystic cavities, one expanding the base of the coracoid process and two in the neck of the scapula. These were exposed at operation and found to contain a jelly-like substance. They were curetted out and the cavities obliterated by removal of the superficial wall. A culture gave *Staphylococcus aureus* only and microscopical examination of scrapings showed a vascular type of granulation tissue.

Mr. Ogilvie's reasons for showing the case were, firstly, the contrast between the widespread periostitis, as seen in a radiogram taken by Dr. G. H. Stebbing four years ago and that of localised central abscesses in a second taken three weeks ago; and, secondly, the unusual site for a Brodie's abscess. Alexis Thompson in 1916 had collected 161 cases, of which 119 were in the tibia, the remainder being divided between the femur, humerus, radius, and ulna. No cases had been reported in the scapula. There was a good deal of confusion as to what was meant by Brodie's abscess. Many text-books mentioned central abscesses of bone only as a tuberculous condition. Some authors confined the term Brodie's abscess to a chronic central abscess of the tibia, while others included all abscesses of a similar pathology. Brodie's description was based on nine cases, all in the tibia; but he clearly recognised the condition as one not limited to any particular bone. It was surely better, if the term Brodie's abscess was to be retained, to include all chronic abscesses of bone septic in origin, in whatever bone they might occur. The point brought out by Thompson that Brodie's abscess is liable to follow mild attacks of infection rather than those in which an acute process has gone to sequestrum formation was well illustrated by this case. The process was acute in the tibia and femur and these bones now showed only periosteal thickening, while in the scapula a milder infection had resulted in the persistence of still living cocci in the interior of the bone and the appearance of central abscesses four years later.

Mr. A. W. SHEEN showed a case of

Abdominal Tumour

a man aged 26. He had had malaria, sandfly fever, and dysentery during the war, and in August, 1920, when before a medical board for malaria, complained of a pain which had recently developed below his left ribs, and was recommended to hospital. The pain became worse, particularly after exertion.

In March, 1921, he was admitted to hospital, having continued at his work until the day he came in. He had become slightly thinner. He was seen to be a thin, apparently healthy man. In the left umbilical region was an abdominal tumour, the size of an orange, and reaching to the mid-line with its lower border at the transverse umbilical level. It was smooth, firm, slightly movable, and had a communicated aortic pulsation. It was slightly tender on pressure. An intermittent pain, worse after exertion, was referred to its region. A barium meal showed a normal alimentary tract, except that there was a bulge at the left end of the greater curvature of the stomach, not in the situation of the tumour. Early in April he was seen again. The tumour was difficult to make out clearly, there being only an indefinite tender fullness.

Among numerous diagnoses which had been made those which, to Mr. Sheen, appeared to be most probable were displaced kidney, tumour of stomach, cyst of tail of pancreas. He proposed to operate and report later. At the meeting the tumour was again quite distinct.

Dr. BERNARD MYERS showed

A Case for Diagnosis.

It was that of a girl, aged 13 years, who had attended hospital in February complaining of swelling of the stomach. She was found to be moderately developed and mentally to be up to the standard. A distinct yellow tinge of the conjunctivæ and skin was present, and apparently had existed since the age of 7. It was said to become a little worse when she caught cold. Telangiectases were noted on the cheeks and forehead. The spleen and liver were both increased in size, the former extending to one inch below the umbilicus, and its right border crossing the middle line of the body. It was moderately firm and not tender. The liver extended from the fourth rib in the right nipple line to three fingers-breadth below the costal margin. It seemed to be rather hard and what appeared to be little nodules were palpable on its anterior surface and lower border. One small area was a little tender. There was no ascites. The apex beat of the heart was in the fourth space in the nipple line and a reduplicated first sound was heard at the apex. At the apex of the right lung there were slight impairment, harsh breath sounds, and increased expiration and vocal resonance. Some moist sounds were audible over this area and most of the right front. The urine contained a trace of bile but was otherwise normal. The tongue was fissured. A few lymphatic glands could be felt in the neck and a doubtful one over the internal condyle of the right humerus. There was no history of a similar case in the family. The patient had apparently had no symptoms until she was 7 years old, but since then had never been quite well and had suffered from slight epistaxis. Banti's disease seemed to be negatived by the absence of hæmatemesis and ascites and by the leucocyte count. The leukæmias were excluded by the blood examination and the history. The case seemed possibly to be one of acholuric jaundice of the Hayem type. The fæces were coloured normally, the urine contained a distinct trace of bile, and initial hæmolysis occurred between 0·45 and 0·5 per cent. saline, with total hæmolysis by naked eye at 0·275 per cent. and by microscope at 0·2 per cent. It was necessary therefore to look elsewhere for the diagnosis. The history in some ways was like that of Hanot's cirrhosis, but not altogether, nor was the liver typical of that complaint. The first Wassermann reaction was negative, a second by another pathologist two weeks later doubly positive, and a third by a different pathologist was negative. It was decided, however, to give glucosegalyl, 0·02 g. intramuscularly every fortnight, and also intramuscular injections of ½ gr. of mercury in cream form, and hyd. c. cret. gr. 1, with pot. iodid. gr. 4 were administered three times a day. After a month's treatment the spleen had become a little softer and slightly smaller. The liver was a finger's-breadth less than formerly. The icteric tinge had diminished a little, and she stated that she felt better generally than she had done for some years.

Mr. B. S. SIMMONDS showed a case of

Gunshot Wound of the Right Arm,

with fracture of the humerus and lesion of the musculo-spiral nerve.

The patient had been wounded in February, 1918; the wound healed in June, 1918, but had broken down twice afterwards. In January, 1919, exploration of the musculo-spiral nerve revealed a gap in its continuity of four inches, and it was found impossible to bring the ends together. In May, 1919, tendon transplantation was performed with success, the pronator radii teres being transplanted into the extensores carpi radiales longior and brevior, the palmaris longus into the extensor ossis metacarpi and primi internodii pollicis, the flexor carpi radialis into the extensor communis digitorum and the flexor carpi ulnaris into the extensor secundi internodii pollicis and extensor indicis. The after-treatment consisted of splinting the wrist with the thumb and fingers in hyperextension, and in re-education.

Mr. SIMMONDS also showed a case of

Gunshot Wound of the Left Shoulder and Chest,

which had been accompanied by fracture of the left clavicle and first rib, lesion of the brachial plexus, lesion of the axillary artery and vein, and hæmothorax.

The patient, a man, aged 22, was wounded in October, 1918, his wound being healed in March, 1919. Examination in May, 1919, revealed a complete lesion of the brachial plexus. In June of that year the plexus was explored by division of the clavicle and of the pectoral muscles. The fifth, sixth, seventh, and eighth cervical and first dorsal roots were found to enter a dense mass of scar from which the cords of the plexus emerged. Faradic stimulation of the roots gave no result and the scar tissue, including the plexus, was excised. Nerve suture was performed as follows: the fifth cervical to the posterior cord, the sixth cervical to the outer cord, and the seventh cervical to the inner cord. The clavicle and pectorals were then sutured. When seen in October, 1920, weak voluntary contraction had reappeared in the biceps and weaker in the deltoid. A faradic response was obtained in all the muscles and there were evidences of regeneration of sensation. Examination in January, 1921, showed voluntary contraction in the deltoid, biceps, triceps, supinator longus, extensor carpi radialis longior, and extensor carpi radialis brevior.

SECTION OF SURGERY: SUBSECTION OF ORTHOPÆDICS.

EXHIBITION OF CLINICAL CASES.

A MEETING of this section of the Royal Society of Medicine was held on April 5th, Mr. E. LAMING EVANS, the President, being in the chair. Among the cases shown and reported were the following:—

Mr. A. H. TODD showed a case of

Chronic Arthritis of the Knee

in a syphilitic boy aged 9 years. He was one of four children, three of whom were living. There were no miscarriages.

He first attended hospital in June, 1918, complaining of "pains all over," on and off, for a month, and that at the beginning of the attack his skin had come out in blotches. His deep reflexes were normal and his nutrition was good. The knee contained no fluid, it was not tender, and his temperature was normal. The diagnosis then made was tuberculosis of the right knee-joint, with erythema nodosum, and fading secondary nodules on the legs and arms. The Wassermann reaction was positive. He continued to limp till December, when he had pains in the hips and ankles, and then pain and swelling of the right knee, lasting for over three weeks; his heart was found to be normal. He was admitted with a diagnosis of ? rheumatism, but the pain, fluid, and swelling persisted in spite of rest and salicylate treatment. In February, 1919, a splint was applied, and a week later the movements were described as "fairly free and painless," but there was much more peri-articular thickening. Pot. iodid. was now administered for the first time, and was continued for more than a year. In March, 1919, the Wassermann reaction was still positive. The condition fluctuated in severity till June, by which time (the limb being in plaster) the pain had subsided somewhat. The Wassermann reaction was now negative. In August, 1919, he was admitted to hospital, and a calliper splint was applied instead of the plaster, and between then and now he had been readmitted several times to have the knee straightened.

At the present time the knee was still puffy, especially on the inner side above the patella; the thigh was one inch wasted, there was tenderness on moving the patella laterally across the femur, and flexion was much limited. The Wassermann reaction was negative. The teeth and eyes were normal and the patient showed no signs of congenital syphilis, except that he was somewhat deaf; the aurist could find no lesion of his auditory nerve. The skiagrams showed marked rarefaction of the bones of the right knee-joint, together with considerable erosion of the articular cartilages and the surface of the underlying bone. The appearances were very like those seen in tuberculous disease of the knee-joint, but the destruction of the articular surfaces was rather greater than would be expected in a knee that showed so little evidence of activity at the present time.

The main interest of the case lay in the question of whether the condition was one of true syphilitic arthritis or one of tuberculous disease in a syphilitic child. Mr. Todd said that when he was an out-patient officer at Guy's Hospital he had Wassermann tests made as a routine upon all patients who had any sort of chronic arthritis; some of them proved to be positive, and of these particular cases some presented close analogies to tuberculosis, whilst others looked like rheumatoid arthritis or even osteoarthritis. While he was careful not to assume that a positive blood test meant that the disease present was actually caused by syphilis he gave salvarsan to all those who had positive reactions, and some of them not only got well rapidly but remained permanently well. That opened his eyes to the fact that numerous cases diagnosed as tuberculous or other chronic arthritis were really and truly syphilitic, and he advocated the examination of all patients who had chronic arthritis of any sort by the Wassermann test as part of the routine examination. It had been suggested that syphilitic persons were more liable than normal persons to tuberculous infection. That seemed to him to be a confusion of thought, and we could draw an analogy from other groups of known syphilitic cases; children with syphilitic keratitis were certainly syphilitic, yet their general health was often very good, and he did not remember ever having seen one of them with a tuberculous joint. In his experience syphilitic joints rapidly got well under vigorous antisyphilitic treatment if they were diagnosed early, and they healed very slowly or not at all if antisyphilitic remedies were only used late in the case. In the case shown it might be argued that the persistence of pain, swelling, and limitation of movement after so much treatment were in favour of tuberculous disease. On the other hand, the left knee seemed to him to be not quite normal; the posterior surface of the patella in the radiogram showed a distinctly crenated and rather fuzzy appearance, which was different from the very clear and definite outline of the normal bone at this age. If that indicated that the left knee was also involved it would be a strong point in favour of syphilitic arthritis, and would make a diagnosis of tuberculosis much less probable.

Dr. W. T. GORDON PUGH said that cases of congenital syphilis were not infrequently admitted to Queen Mary's Hospital, Carshalton, as tuberculosis, especially cases with glands of the neck. With regard to joint affections, in syphilis of the knee the condition was generally symmetrical and cleared up after administration of kharsivan.

Tuberculous Dactylitis.

Mr. P. MAYNARD HEATH showed a case of Tuberculous Dactylitis in an unmarried woman aged 31.

Her illness began ten years ago with enlarged glands in the neck. She was taken to hospital and was said to have enlarged glands all over her body. Seven years ago the right thumb became painful, and swelling followed in two or three days. The pain ceased after two months. Gradually all the fingers became affected. A gland in the neck was aspirated four years ago, and this was followed by the appearance of lupus on the face and neck. She had been treated for ulceration of the cornea five years ago, and had suffered from winter cough since the age of 7. There had been an attack of hæmoptysis at Christmas, 1920, and on four occasions since. There was no definite history of tuberculosis in the family except that the mother's sister had two daughters suffering from phthisis. At the present time the hands were extensively crippled by firm swellings, apparently involving the tendon sheaths of all the digits. Considerable deformity was produced and the movements of the fingers and thumbs were limited. The glands on both sides of the neck were enlarged and there were patches of lupus on the face and neck. There were signs of phthisis in the upper lobe of the right lung.

X ray examination of the hands showed discrete areas of rarefaction scattered through all the bones. There was no new bone formation. X ray pictures of the feet showed a similar condition, though clinically the feet were unaffected. No changes had been detected in the long bones. The Wassermann reaction was negative. The hands had been treated by Bier's passive congestion, the application of dry heat, and the inunction of collloidol iodine oil. Very slight amelioration had been produced.

Finger Injury.

Mr. A. W. **SHEEN** described the case of a woman aged 49, who, in December, 1920, fell and dislocated her left ring finger at the proximal inter-phalangeal joint, the finger being bent to the ulnar side. She pulled it in herself. Subsequent treatment was by massage and movements, and later by strapping of the joint. The pain and swelling which were present became less, but did not disappear. X ray examination in February, 1921, showed a chip fracture of the distal end of the proximal phalanx on the ulnar side. She was now being treated by massage, hot air, and ionisation, and, as an inability to extend the finger completely had developed, a small splint was worn to pull the finger into full extension. Swelling was still present, pain was slight and intermittent, and active movements were good. Sagittal and lateral skiagrams were shown.

The **PRESIDENT** showed a case of

Bilateral Radio-Ulnar Synostosis

associated with Bilateral Congenital Dislocation of Hips in a girl aged 5, who was first seen in May, 1918. The mother complained that the child was unable to roll the forearms. The patient had three sisters and one brother without deformity, and there was no history of deformity in the family. A synostosis of the upper ends of the radius and ulna were present on both sides, the forearms being in position of pronation. In the routine examination of the child for other deformities it was found that a bilateral congenital dislocation of the hips was present. These were reduced in September, 1918, and a radiogram was shown before reduction and one taken in February, 1921, which confirmed the physical findings that the treatment had been successful. He had not attempted to treat the radio-ulnar synostosis because (1) the functional disability was slight and could be compensated to a large extent by external rotation of the shoulder, and (2) attempts at nearthrosis had resulted, in the cases he had seen, in failure.

Mr. D. **MCCRAE AITKEN** reported that he had recently had a case of synostosis of the radius and ulna in a girl of 13, otherwise well developed and intelligent.

The synostosis involved the superior radio-ulnar joint and extended nearly to the bicipital tuberosity. An operation was performed on the left arm, when an incision was made along the posterior border of the ulna, the anconeus separated from its insertion to the back of the olecranon, and the whole block of bone between the radius and ulna removed, including a considerable portion of the adjacent parts of both bones. When taking out this block of bone the portion of muscle attached to the coronoid processes was pulled right through to the back. This was secured to the edge of the anconeus, and when released pulled the anconeus as a complete buffer between the two. Free rotation was possible at the time. The operation was performed three days ago, and Mr. Aitken said that he would report the result in six months' time.

The **PRESIDENT** also showed a case of

Multiple Cartilaginous Exostoses,

associated with congenital dislocation of hip in a girl aged 9, who was first seen at age of 2 years and 9 months in October, 1914.

The left leg was noticed to be shorter than the right, and examination showed a dislocation of the left femur on to the dorsum ilii. Nothing abnormal could be detected either on the femoral head or at the site of the acetabulum. A thickened mass could be felt on the anterior surface of the left femur below the level of the great trochanter and a small irregular mass on the crest of the right ilium. It was noted at the time that these masses were of the nature of cartilaginous exostoses. The child was not seen again until March, 1921, when the case had then developed into a typical one of multiple cartilaginous exostoses. There was no history of deformity in either the father's or mother's family. One sister and two brothers were normal. Exostoses could be felt on the left femur at the insertion of the adductor magnus, and at its upper end on its anterior surface just below the level of the great trochanter, on the left tibia at the insertion of the sartorius, and at the lower end of the left fibula. The X ray appearance of the left acetabulum strongly suggested a cartilaginous exostosis rising from the Y-shaped cartilage, but this could not be onfirmed by palpation. Exostoses were also present on right iliac crest, right femur, and right fibula, the lower d of the right radius, and the vertebral borders of the pulæ.

The **PRESIDENT** considered that this was a case of so-called congenital dislocation of the hip in which the cause had been a shallowing of the acetabular floor caused by a cartilaginous exostosis arising from the Y-shaped cartilage, and projecting above the level of the floor of the acetabulum.

ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.

A **MEETING** of this society was held in the Faculty Hall on March 18th, Professor **WALTER K. HUNTER**, the President, in the chair.

Mr. J. **MILL RENTON** made a communication on

The Surgical Treatment of Chronic Sciatica.

He thought that the benefits of surgical treatment were not widely recognised, possibly on account of a lack of appreciation of the type of case suitable for operation, and also possibly because nerve stretching is an unsatisfactory operation. He advocated, in suitable cases, nerve freeing. To ensure success the diagnosis must be correct and non-inflammatory causes of sciatic pain ruled out before the operation is undertaken of nerve-freeing. Mr. Renton divided cases of chronic sciatica into three groups:—

1. Cases where the patient is quite free from pain while at rest but begins to have pain on exercise or on assuming some special position.
2. Cases where there is a certain amount of pain during rest, which becomes really intense on exercise or on the assumption of a particular position.
3. Cases where the pain is indefinite, present at rest off and on, and sometimes improving to a certain extent on exercise.

In the first type of case the inflammation has subsided and left adhesions and even bands of adhesions which drag on the nerve. This type of case is pre-eminently suited for nerve-freeing. In the second type of case there is presumably also some degree of inflammation of the nerve still present, which is possibly kept up by the pull of the adhesions. In a majority of cases operation benefits these cases but not in all. In the third type of case the pathology is not clear and operation does not seem to benefit the condition. The operation consists in exposing the nerve and removing all adhesions from the sacro-sciatic notch to the middle of the thigh. A certain amount of stretching of the nerve is unavoidable, but the principal part of the treatment is the separation of the adhesions.

Injury of the Thoracic Duct.

Mr. G. H. **EDINGTON** read a short account of two cases in which the thoracic duct was injured in the operation for removal of tuberculous cervical glands.

Early in 1911 he operated on a boy, aged 7, for tuberculous cervical glands involving an extensive dissection on the left side of the neck. The thoracic duct was not seen and there was nothing unusual in the wound at the conclusion of the operation. There was post-operative rise of temperature to over 100° F., and in 36 hours the dressings began to be soaked with watery discharge. On the fourth day the wound was opened and fluid sponged out; the welling of fluid had ceased, but the jugular vein was found to be very fragile. There was no pus in the wound and the muscles were peculiarly clean and bare. Death took place on the night of the sixth day with a copious flow of blood from the wound.

On the second case, a woman aged 28, Mr. Edington had operated in the summer of 1920. Extensive dissection on the left side of the neck was required, but the thoracic duct was not identified. The following day there was copious watery discharge, and two days later there was ballooning of the lower part of the neck, and through the lower incision there spouted fluid like whey, of a pale-greenish colour. The temperature rose to 101°, and, as milky fluid continued to pour out, the cavity in the posterior triangle was packed with gauze. The tissues in this case also were macerated. After the firm packing of the posterior triangle the milky discharge became gradually less, and the wound healed without further event.

In the discussion Mr. **ARCHIBALD YOUNG** recorded a third case of a man, aged 52, whom he operated on in 1910 for a very extensive tuberculous involvement of the cervical gland on the left side.

Dissection of the glands was carried out laboriously and with much difficulty, and the sterno-mastoid muscle, part of *the parotid gland, and part of the internal jugular vein were* removed in the course of the operation. During the operation *Mr. Young* became aware, *through soaking of his gown* and the sheets on the operating table with a glairy, sticky *fluid, that injury of the thoracic duct had taken place.* An attempt was made to find the injured duct but without success, and in the end recourse was had to packing with iodoform gauze. From the time of the operation there was *no further escape of chyle, and on the removal of the packing*, which was not disturbed for several days, it was found *to be soaked with serum only. Recovery was uneventful.*

Mr. J. Hogarth Pringle, Dr. L. T. Stewart, and Professor J. H. Teacher made a communication on

Digestion of the Œsophagus as a Cause of Post-operative and Other Forms of Hæmatemesis.

The main points in the paper, which was illustrated by specimens, sections, and lantern slides, were as follows:—

Post-operative hæmatemesis is a *symptom of great* importance to the practical surgeon and associated with serious danger to the patient. In recorded cases various explanations are given, but digestion of the œsophagus is not mentioned. A few cases of intra-vitam œsophagomalacia and ulcus a digestione have been recorded, and in July, 1914, Glynn demonstrated to the Pathological Society of Great Britain and Ireland, sections of the œsophagus which showed ulceration and inflammatory *reaction. Prior to* January, 1914, one of us had seen two cases of destruction of the lower part of the œsophagus which looked *as if it might* have commenced during life. Then a case occurred under Mr. Pringle in which vomiting of brown material was observed after operation and about 36 hours ante mortem. There was also complaint of pain behind the *sternum. No* cause of these except the digestion of the œsophagus (which had not gone the length of perforation) could be *made out and* the observation then ceased to be a pathological curiosity and became a matter of practical importance. In 1919 the authors made a communication to the *British Journal of Surgery* (Vol. VI., No. 24, p. 523) on this subject. In that article they described a number of cases in which digestion of the œsophagus appeared to have been the cause of hæmatemesis or vomiting of brown or black material, and in some cases the cause of death. Several of the cases in the series were not surgical but medical cases —e.g., anthrax, pneumonia, and puerperal eclampsia. On clinical and morbid anatomical grounds the digestion of the œsophagus was regarded as a vital phenomenon. Sections from a number of these cases were shown to the Pathological Society at the meeting in Leeds in January, 1921, and full publication will be made in the *Journal of Pathology and Bacteriology*. A short abstract of the communication appears in the *Journal* (Vol. XXIV., 1921, pp. 119-120), in the Proceedings of the society.

Intra-vitam digestion of the œsophagus is supposed to arise in the following manner: Vomiting of active gastric juice occurs, but the œsophagus fails to clear itself and some of the fluid remains in it, accumulating particularly just above the cardiac sphincter, in which region the injury to the tube is usually most advanced. In post-operative hæmatemesis the fluid ejected is usually extremely acid, and those patients who are sufficiently conscious to be able *to express* themselves frequently complain of the scalding effect which it has upon the throat and lips. The lesions produced ante mortem by gastric juice which has escaped into and lain in the œsophagus are apt to be more or less *obliterated* by changes due to continuation of the digestion post mortem. In 12 of the 15 cases which were *described in 1919*, and 4 new ones, however, microscopic examination has revealed unmistakable signs of vital reaction *in the form of* abundant leucocytic infiltration of the mucous membrane and other tissues, congestion of blood-vessels, accumulation of leucocytes in the vessels, thrombosis, and inflammatory œdema. The picture is that of an acute *ulceration*. It is easier to recognise these changes than to assess the extent to which they may have been obscured or *obliterated* by continuation of digestion, or to decide the relative amounts in which that digestion is a continuation of *the lesion* which developed during life or a post-mortem change. Probably these cases have been observed, but the *lesions have* been put down as merely post-mortem digestion, from which, however, we do not now find it difficult to distinguish them. It is therefore clear that digestion of the œsophagus during life does occur, that it may be the cause of death, *that it* occurs in other than operation cases, and that it may be arrested and healing take place. Its occurrence *is shown by* hæmatemesis, and in some cases by pain behind the sternum. It is therefore open to diagnosis, and must, *in some cases* at any rate, be amenable to treatment. The commencement of healing has been recognised in two specimens.

In *most of the cases recorded* in the *Journal of Surgery* the digestion probably began not more than 36 hours before the death of the patient; in some cases the *duration* was much less, reckoning from the occurrence of the hæmatemesis. The *morbid anatomy of the cases* showed *great variation, from* slight condition in which the phenomena were superficial *erosion of the mucous membrane* with *hæmorrhages into* the affected tissue and black fluid in the œsophagus to cases *in which perforation or extreme maceration of the lower* third of the œsophagus and extensive digestion of the *adjacent surfaces of the lungs had taken place.* Nine examples of the most advanced type, five severe but not *perforated, and five slighter lesions* have been observed—17 of them since January, 1914.

A *most important diagnostic* feature available at post-mortem examination is the relatively slight change in the *stomach, which may show only slight* post-mortem digestion *or* a total absence of that condition, contrasting with advanced *digestion of the* œsophagus immediately above the cardiac ring. In most cases, at least of the severer types, *there is a well-marked zone* of deep ulceration immediately above the cardiac ring. At a varying distance above this the *changes* are less of the nature of destruction, the predominant features being superficial erosion and hæmorrhages *into the* mucous membrane, such as are seen in the slight cases. Signs of reaction may be unrecognisable or *very slight* in the lower parts, but well marked in sections prepared from the upper parts of the damaged œsophagus.

Mr. G. H. Edington and Dr. A. S. Strachan showed a card specimen of a Pendulous Fibroma *of the* Labium Majus suggesting at first sight pseudo-hermaphrodism, taken *from* an aged *female* subject in the dissecting-room. A microscopic section of the tumour was also shown.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

Exhibition of Cases and Specimens.

A clinical meeting of this society was held at the West London Hospital on April 1st, Dr. F. J. McCann, the President, in the chair.

Mr. Aslett Baldwin *showed* a case of Recurrent Dislocation of the Hip in a girl of 17, the subject of old-standing poliomyelitis *affecting the whole lower limb.* Recurrence of the dislocation had not taken place since the hip had been placed in plaster *after reduction in the* abducted position four years ago. Since the final reduction the limb had *developed considerably.*

Mr. B. Sangster Simmonds showed: (1) A case of Persistent Headache and Recurring Fits, following gunshot wound of the parietal bone. The case had been treated by Sergeant's method of inserting celluloid plates, after the brain had been released from its adhesion to the scalp. *Since* operation headache and fits had ceased completely. (2) A case of Gunshot Wound of the Knee in which an arterio-venous aneurysm of the popliteal vessels had been successfully removed. (3) A man in whom a Largely *Functional* Ataxia had followed a temporary organic paralysis. (4) A case of Functional External Popliteal Nerve Paralysis *following* a gunshot wound of the thigh.

Mr. Neil Sinclair showed radiograms of an Ossifying Ecchondroma of the Upper End of the Humerus in a boy of 9. The tumour was solitary.

Dr. W. N. Goldsmidt showed: (1) A case of Friedreich's Ataxia in a girl of 17. No other member of the family was affected. (2) A boy of 15 with Congenital Syphilitic Liver and Spleen. Tumours were present in the liver and spleen, and there was a positive W.R.

Dr. Clifford Ellingworth *showed a case of* Myelocythæmia in a woman. Attention had been directed to the large spleen when the *patient* was *under treatment* for excessive bleeding following a miscarriage. The blood changes were typical.

Dr. W. R. Marshall showed: (1) A case of Pernicious Anæmia improving under *treatment* with neoarsenobillon injections. (2) A case of Colitis in a woman. Full investigation of the cause *of the condition had not* been completed yet.

A discussion *on the* Diagnosis and Treatment of Colitis followed, in which the President, Drs. A. Baldwin, H. W. Chambers, Vaughan Pendred, Rickard Lloyd, W. N. Goldsmidt, S. D. Clippingdale, and D. G. Rice-Oxley took part. The importance of *sigmoidoscopic examination* was referred to. The influence of diet as a cause and in the treatment of the condition was *emphasised*. Bacteriological examination of the fæces and treatment by vaccines was part of the routine *treatment. The influence* of climate was also commented on by several members.

Reviews and Notices of Books.

ORTHOPÆDIC SURGERY OF INJURIES.

By Various Authors. Edited by Sir ROBERT JONES, K.B.E., C.B., F.R.C.S., Director of Orthopædics, St. Thomas's Hospital; Honorary Adviser to the Ministry of Pensions (Orthopædic Surgery). London: Henry Frowde and Hodder and Stoughton. 1921. In two volumes. Vol. I., pp. 540; Vol. II., pp, 692. £4 4s.

THESE two handsome volumes embody the principles and practice of the British orthopædic centres and special surgical hospitals in and after the Great War. To their editor belong the honour and credit of having organised and directed this great work, with which he was entrusted by Sir Alfred Keogh, who selected a man pre-eminently qualified to inspire all under him with his energy and enthusiasm. It would be a calamity if the knowledge acquired in the practice of war orthopædics, which is largely applicable to the treatment of the injuries of peace, were lost for want of an adequate record, and it would have been discreditable to British surgery if such a work as the "Traité de Chirurgie Reparatrice et Orthopédique" were to have no counterpart in this country.

Sir Robert Jones gives an interesting account of the genesis of the special hospitals, and of their increase from 250 to nearly 30,000 beds as the need for specially skilled treatment increased. He emphasises the immense superiority of voluntary over passive movement, and he rightly asserts the necessity of a thorough knowledge of general surgery in the surgeon who would succeed in orthopædic work.

The article by Professor Arthur Keith on the Principles and Practice of Hugh Owen Thomas amounts to a dedication of these volumes to the memory of that brilliantly original surgeon, who was so little appreciated by his contemporaries, and whose inventions have probably been the means of saving the lives or limbs of thousands of wounded soldiers. Sir H. M. W. Gray brings this out clearly in his article on the prevention of deformities, in which he deals with first-aid, the transport of the wounded, and treatment in casualty clearing stations. In one army alone, after the use of the Thomas splint had been demonstrated in all the field ambulances, the mortality from fractured femur was reduced from 50 to 15·6 per cent., and in this series the proportion of amputations was only 17·2 per cent.

Colonel Goldthwait, who was senior consultant in orthopædic surgery to the United States Expeditionary Force, also recommends the Thomas splints in the first treatment of wounds and sets forth his well-known views as to the importance of posture and of weak or flat feet.

The treatment of simple fractures in our civil hospitals had fallen into a bad way. The brilliant advance of abdominal surgery so dazzled the eyes of surgeons and students that they could not see the great importance of adequate knowledge and experience of the treatment of fractures of the limbs. Fractures of the lower extremity were either not admitted to the wards or when admitted were treated as beneath the notice of visiting surgeons.

The article by Mr. W. H. Trethowan on simple fractures deals duly with principles as well as details and should prove useful and suggestive to all who would adequately treat these injuries. The uses of central and external bone grafts and of plates are well considered, the latter being preferable only when great strain has to be borne during the process of union. A valuable hint is given as to fractures of the toes: "a minor fracture may give a major disability." In no department of surgery have greater advances been made than in the splinting of war fractures, and this is treated by Dr. Henry G. Carlisle in a chapter well illustrated with photographs.

Mr. W. Hey Groves was well known before the war for his original methods of treating fractures, and the article on ununited fractures is safe in his competent hands. The details and the good results of the bold and ingenious procedures adopted by him are well shown in his diagrams and radiographs. The editor himself deals very briefly with the subject of mal-union of the femur and the procedures necessary for its correction; he never uses plates. Chronic osteomyelitis and the persistent sinuses and suppuration which have been so troublesome to surgeons and patients are dealt with by Mr. R. C. Elmslie succinctly and clearly.

Mr. Naughton Dunn and Mr. S. W. Daw describe the treatment of disabilities of joints of the upper extremity above the wrist, showing the good results of their treatment. Dr. Walter Baldwin, of San Francisco, deals with the hand and wrist, and points out how all important is function in this region, where, as he says, no criterion other than function can be of the slightest interest to the patient applying for relief. We suggest, however, that appearances are often given great importance by the patient. Since stiff joints of the fingers and hand are, unfortunately, common as the result of war injuries and are equally disabling and resistant to treatment, the recommendations of Dr. Baldwin are sure to arouse interest. The ingenious splints employed by him are well shown in the illustrations.

Dr. F. C. Kidner, late consultant to the United States Expeditionary Forces, gives a brief account of disturbances of the lumbar spine and pelvic girdle. These conditions have not received so much attention here as in America, and the ætiological relation between some cases of sciatica and subluxations of the pelvic joints is not generally recognised. The subject deserves more study in this country. An excellent article on the knee-joint, contributed by Mr. Alwyn Smith, deals with injury and with secondary conditions such as arthritis.

In an important article on ankylosis and stiff joints, Sir Robert Jones confines his remarks to the later treatment to which joints injured in the war must be subjected. As regards early treatment, he insists on the supreme importance of the principle of relaxation of damaged structures such as ligaments, of far more importance at an early stage than any form of physiotherapy. His advice on the breaking down of periarticular and articular lesions is clearly set forth and of peculiar value. For the successful treatment of the conditions found in stiff joints great experience and sound judgment are required; Sir Robert Jones places his own unreservedly at the disposal of the reader. His article on the treatment of flail joints also is full of practical wisdom and instruction.

Mr. Elmslie writes briefly on amputation and artificial limbs, and the conclusions to which he comes will be approved by surgeons familiar with these subjects. Sir John Lynn Thomas describes the limb-fitting centre at Cardiff.

The second volume is devoted to injuries of the nervous system and their treatment, to so-called purely functional disabilities and their treatment, and to physiotherapy, &c. This volume is surely unique in surgical literature, in that it contains an article by a lately reigning monarch. Ex-King Manuel of Portugal contributes an article upon curative workshops, a subject that he made peculiarly his own at Shepherd's Bush, where he did so much to help forward the work of rehabilitation of the disabled. The subjects here dealt with are not so completely surgical as those of the first volume, some of them being written by physicians, but they are all subjects which may not be neglected by orthopædic surgeons.

The anatomy of the spinal nerves is well treated in the article by the late Professor A. Melville Patterson, the diagnosis of their injuries by Dr. Grainger Stewart and Mr. Rowley Bristow, the prognosis by Dr. Farquhar Buzzard, operative treatment by Sir Harold Stiles, post-operative treatment by Mr. Rowley Bristow, and end results by Mr. Beresford Alexander, some of whose conclusions have already been published in the *British Medical Journal*. An analysis of 500 cases of peripheral nerve lesions which passed through Alder Hey Hospital, and could afterwards be traced, showed as a result 35 to 44 per cent. of recoveries. The same subject is treated by Dr. Maud F. Forrester Brown, who studied the results obtained at the Edinburgh War Hospital at Bangour. Failing recovery after nerve suture, &c., tendon-transplantation and tendon-fixation have given most gratifying functional results, especially in musculo-spiral nerve lesions. This subject is well presented to us by Mr. T. P. McMurray. Dr. Buzzard and Mr. Percy Sargent write of injuries of the head and spine. These articles are, as might be expected, accurate and informing. An interesting chapter by Dr. J. le F. Burrow and Dr. W. Cuthbert Morton deals with functional and reflex disabilities and their cure. In the experience of the writers hysteria uncomplicated by wound or other injury was rare among soldiers.

In the course of the treatment of the many nerve lesions of the war anomalous and puzzling voluntary movements have sometimes been noticed, when the muscles which normally produce these movements are completely paralysed. The Croonian lectures on muscular movements by the late Dr. C. E. Beevor did not receive the notice and appreciation they deserved, and it is gratifying to find that a somewhat similar study has been undertaken by Professor F. Wood Jones, D.Sc., who has had the great advantage over Dr. Beevor of being able to test the muscles electrically when they are exposed on the operating table. He shows how many and how remote the muscles may be that are pressed into service in attempting to perform a movement, when the proper muscles are paralysed, and what caution is necessary before we assume that, for example, because the patient is able to flex the elbow the musculo-cutaneous nerve is not completely divided. "No man can flex his wrist with his platysma, but ...... many men will attempt it." The photographs reproduced in this chapter are most illuminating. The ancillary but most important subjects of splints and plaster are adequately treated by Mr. McCrae Aitken, plain metal splints by Mr. Lane Joynt, the electrical department by Mr. Rowley Bristow, massage by Dr. J. B. Mennell, the Ling system by Dr. Murray Levick, hydrotherapy by Dr. Fortescue Fox, while orthopædic X ray work has been entrusted to the competent hands of Mr. Thurstan Holland, who records the startling fact that there are some 250 methods of locating foreign bodies. The comparatively simple method described by Mr. Holland has given good results and stood a long test. The double exposure method both with screen and plate has been shown to be thoroughly sound and useful, although in unaccustomed hands it may not be so immediately convincing as the stereoscopic method, which is also described. Dr. Holland's work in his specialty is so well known that it is hardly necessary to state that his contribution to this volume is of great value.

Dr. Walter de M. Hill's article, although the last in the book, is not the least informing. He gives an account of the organisation and equipment of a special military (orthopædic) hospital of 1000 beds, which is interesting as a record and as a guide to future possibilities.

As the editor admits in his preface, it is very difficult to define orthopædic surgery. No operations or appliances can be differentiated as peculiar to orthopædics, but there is an attitude of mind which is definitely orthopædic and which sets forth the restoration of function as the end and aim of treatment. Operating surgeons have been too apt to consider their work done when the operation wound is healed. The orthopædic surgeon considers that his task is often scarcely begun at that stage, although much preoperative work may be necessary; operations may be only minor events in the course of successful treatment.

PHENOMENA OF MATERIALIZATION.

A Contribution to the Investigation of Mediumistic Teleplastics. By Baron VON SCHRENCK NOTZING, Practising Physician in Munich. Translated by E. E. FOURNIER D'ALBE, D.Sc. Lond. and Birm. London: Kegan Paul, Trench, Trübner, and Co., Ltd.; New York: E. P. Dutton and Co. 1920. Pp. 340. 35*s.*

THIS is a monograph of considerable size and profusely illustrated dealing with the particular phase of mediumship usually called materialisation and termed by the author "mediumistic teleplastics." From the preface to the first German edition, which appeared a year before the war, we gather that Baron von Schrenck Notzing has been earnestly engaged for some time in spiritualistic inquiry, while photographs are published, in evidence of the occurrences related, dating from as far back as 1909. Detailed observations over the same period of time are contributed by a lady who acted as protectress to the medium through whom the more important manifestations were apparently obtained. We have no reason to doubt the complete sincerity of Baron von Schrenck Notzing, but we cannot think that scientific readers will find his work in the least convincing. "Nothing is too wonderful to be true," said Faraday, and quotes the author, but whether the occurrences which are recorded in this work are capable of explanation in accordance with known physical lines or not, it is not a scientific attitude to postulate explanation of any transcendental sort, while simpler explanations can be put forward. This is not to say that we are capable of explaining away all the things that have been said to happen or to comprehend the mechanism by which the photographic appearances may have been obtained, but it is perfectly clear that neither the statements nor the pictures have been subjected to anything like the scrutiny which the pièces d'évidence in an ordinary scientific experiment are bound to undergo.

In a large proportion of the manifestations the medium was one called Eva C——, who seems to have been engaged from youth at séances, and to have lived during a large proportion of the time dealt with in this book under the care of a Mme. Bisson, who was usually present at the conduct of the séances. Why, one must ask in face of the claim of the observation of scientific precautions, was such an obvious opportunity for collusion allowed to continue? It is impossible not to regard the minute safeguards, stated by the translator to be "excessively severe to eliminate the hypothesis of fraud," as a little comical when so excellent a chance for fraud was permitted to go unchallenged. Appeals to the spotless honour of the medium and of Mme. Bisson have nothing to do with the case, the moment the claim is made that scientific precautions have been taken.

We doubt whether this work, imposing though it is in appearance and solemn in claim, will do much to remove scepticism; further, we can even conceive its shaking the faith of those who are already believers in occurrences of "materialisation."

LES CARDIO-RÉNAUX.

Étude théoretique et pratique. Par O. JOSUÉ et MAURICE PARTURIER. Paris: E. Le François. 1921. Pp. 230. Fr.12.

THE problems presented by cardio-renal cases are among the most difficult in both clinical medicine and pathology. In the more obviously cardiac cases with signs and symptoms of heart failure it is a matter of considerable difficulty to determine how far failure of renal function is a complicating factor in the case. And even when a part of the clinical picture is obviously the result of renal inadequacy the clinician is faced with the further difficulty of differentiating between a condition of primary renal inadequacy and one merely secondary to vascular stasis. Genuine renal cases present a similar problem, for in these the difficulty turns on the estimation as to how far an accompanying and relative degree of heart failure is an aggravating factor in the case. It is with these obscure problems that this book concerns itself, and thus fills an important gap in medical literature. The authors take a simple view of their subject and make an important distinction between true and false cardio-renal cases, based on the determination of renal adequacy after cardiac efficiency is restored. The group of "true" cardio-renal cases includes those only in which signs of renal inadequacy persist after cardiac efficiency has been re-established. The authors have been occupied for many years in the investigation of renal efficiency in cardiac and cardio-renal cases, and they have simultaneously made a close clinical study and analysis of their cases. Their results are here collated and presented with originality of thought, clearness of expression, and disregard of many time-honoured conceptions of cardio-renal disease. They discuss the chemico-physical theories of œdema and renal excretion in so far as they are necessary for a proper clinical understanding of the subject, and at the same time their work has an immediate practical interest since it establishes principles on which treatment should be based. Ample references to the current French literature are given. It is interesting to find that this book reflects the present trend of thought in regarding renal disease as cardio-vasculo-renal, a conception that gains less ready acceptance in England, where the classical observations of the late Dr. Richard Bright tend to maintain their dominating influence.

A FIRST COURSE IN GENERAL SCIENCE.

By FREDERIC DELOS BARBER, *Professor of Physics, Illinois State Normal University, and Others.* London: G. Bell and Sons; New York: Henry Holt and Co. 1921. Pp. 608. 9*s.*

A MASTER at a well-known school who had a mind which soared beyond questions of grammar, syntax, and prosody, used to set a paper entitled "A Common Sense Paper," in which the scholars were asked such questions as "Why does the barometer go up and down?" "How does a pump work?" "Why do chimneys smoke?" "What is the difference between the working of a gas light, an oil lamp, and a candle?" and so on. The book now before us supplies the answers to all these questions, and to a great many similar, and is altogether a most useful and informing work. It deals with such matters as the production and use of light and heat, refrigeration and its uses, the weather and the seasons, ventilation, food, micro-organisms, soil, water-supply, machines, work, energy, and applied physics generally.

In the matter of lighting surely the authors are incorrect when they say (p. 6) that "up to about 1860 candles were by far the safest and best sources of artificial light which the world had ever used." The moderator lamps of our fathers' and grandfathers' time, burning colza oil, were perfectly safe, and if properly looked after gave a very good light. The statement above quoted is all the more remarkable, as the authors tell us on p. 101 that coal gas was used for street lighting in Baltimore so long ago as 1817. In the sections on machines, it seems to us that the statement in par. 618 needs making clearer. "A locomotive owes its power to pull a train to the friction between its drive wheels and the rails. The largest locomotive ever built weighs 336 tons and can exert a pulling force of about 60 tons and can easily pull a train of 200 cars, each weighing 50 tons. If this locomotive were attached to a train requiring a force of more than 60 tons to move it, the locomotive would be unable to start the train because its drive wheels would then slip on the rails."

We must note that the test given on p. 365 for distinguishing between butter and butterine or oleomargarine is incorrect, at least as regards the margarine sold in this country, for margarine sputters more than butter when melted. As they both contain a certain proportion of water this must be so, but margarine melts in a different way from butter, owing to the fats of which it is composed having different melting points.

Taking it all round, however, the book is very good, and, except for the passages to which we have alluded, is eminently clear and simple. Anyone who lives in a house should have a knowledge of the problems contained in this book, for not only will he then be in a position to deal with the various troubles which always arise in connexion with water-taps, lighting arrangements and other matters, but he will also be educated in the thousand and one things which are at once the comfort and the bane of civilised life.

THE LOGIC OF THE UNCONSCIOUS MIND.

By M. K. BRADBY. London: Henry Frowde and Hodder and Stoughton. (Oxford Medical Publications.) 1920. Pp. xiv. + 316. 16s.

THE title of this book is somewhat misleading, for it does not deal with any logic peculiar to the unconscious, but with the influence of the unconscious mind on logical thinking. The writer, indeed, denies that the unconscious mind has any peculiar logic of its own, and maintains that "all logic is one, that of rational mind continually developing." Miss Bradby, however, does not give any very explicit account of what she understands by the unconscious mind, and although she deprecates the censure of the psycho-analysts, who declare the unconscious to be non-logical, it seems clear that she is more frequently speaking of the pre-conscious than of the true unconscious of Freud. For whenever the processes of the true unconscious are in question, as, for example, in dream symbolism, it is hard to see how the logic of identity can be discerned, even in the germ. When the dreamer fails "to distinguish the separate and continuous individuality of things," when "it is not unusual for things to turn into each other, and to be each other, and to be the dreamer," all the rules of formal logic must be inapplicable. But Miss Bradby has little love for formal logic. Those processes of reasoning which are expressions of purpose rather than statements of fact are her chief interest, and the source of logical fallacies which affect the conduct of life rather than their formal classification is the main topic of her book. This source she finds in unconscious motives.

> "We may argue from a false premiss, neglect the laws of deductive inference, argue irrelevantly, use words ambiguously, beg the question, argue in a circle, or fail to apply a general principle to a particular case; but the reason we do so is to be found in unconscious interests and emotions. A thinker can only become more logical by discovering in what direction these habitually tend to mislead him."

This is the main theme of Miss Bradby's book, and it is expounded with a wealth of illustrations derived from many different sources, both ancient and modern, and accompanied by a profusion of references which is somewhat intimidating. Typical cases of illogical conduct are given, many arising in connexion with contemporary political and social problems, and the common fallacies to which we are prone are classified and illustrated by examples. The final section of the book deals with "logic applied to life." Education, social problems, the phenomena of spiritualism, love, and religion, are considered in the light of the views put forward in the earlier part of the book. As is said in the preface, "So vast is the subject of this book that only an enthusiastic amateur would dare attack it on so small a scale." And, indeed, the chief impression we get from Miss Bradby's work is one of intense enthusiasm—an enthusiasm for the rational, for freedom in thought and in life, for the cause of the oppressed, and for the progress of humanity.

A HANDBOOK OF SKIN DISEASES AND THEIR TREATMENT.

Second revised edition. By ARTHUR WHITFIELD, M.D. Lond., F.R.C.P. London: Edward Arnold. 1921. Pp. 291. 18s.

DERMATOLOGISTS throughout the world will rejoice that a second edition of Dr. Whitfield's book has at last appeared, for it differs entirely from any other treatise on dermatology. It is not a text-book, but is rather an eminently scientific account of the commoner diseases of the skin, in which the author's own views on their ætiology and treatment are set forth very clearly. For this reason it will be read with great interest by dermatologists, and will be appreciated also by general practitioners and students who have already digested one of the ordinary text-books. The chapter on ringworm infection is particularly good; stress is rightly laid on the importance of eczematoid ringworm of the feet and hands, which, in Dr. Whitfield's opinion, is commoner since the war. The X ray treatment of ringworm of the scalp is described, but a detailed account of the croton-oil method is also given, and will be found useful by practitioners who have no access to X ray treatment.

In his account of staphylococcal infections of the skin Dr. Whitfield states that in several cases of furunculosis he has found the coagulation-time of the blood increased, and he suggests that the apparent beneficial effects of calcium sulphide in some patients may really be due to the administration of calcium. He considers treatment with staphylococcal vaccine of great value, but has found stannoxyl only occasionally successful, and collosol manganese by no means the specific that some writers claim it to be. About the chapter on eczema it may be said that Dr. Whitfield has dealt with this dreaded subject in a very thoughtful and sane manner. With Darier he considers cheiropompholyx merely an acute eczema of the extremities, and points out that some cases of "relapsing dysidrosis" are really epidermophyton infections. It is perhaps unfortunate that the seborrhœides are included in this chapter; we think it would have been better to describe them apart. In considering the ætiology of eczema the author discusses the association of one form with asthma, and thinks that many of these cases are dependent on chronic focal bacterial infection, but the relationship of asthma and eczema to food idiosyncrasy is not considered. The section on the external treatment of eczema is, on the whole, well written, but the management of acute and subacute cases of the disease in seborrhœic persons, which was one of the chief problems of war dermatology, is hardly dealt with at all, and, since the author is convinced that "there is no internal treatment which has the slightest influence on eczema itself," it is not surprising that there is little to be learnt from his remarks on internal medication. The tuberculides are described fairly fully. There is hardly sufficient justification for the inclusion of lupus erythematosus in this group. No mention is made of the treatment of the true tuberculides, such as Bazin's disease, folliclis, &c., by injections of neosalvarsan and of tuberculin.

One of the most interesting sections is that concerning the treatment of syphilis. In the first place Dr. Whitfield attaches very great importance to the Wassermann reaction, provided that it be carried out by a reliable expert, and he insists that the aim of treatment is to establish and maintain a permanent negative reaction. He believes, moreover, in vigorous treatment by neosalvarsan and mercury in patients with a positive reaction, but with no active clinical manifestations of syphilis. As regards mercurial treatment, he considers the oral administration of hydrarg. c. cret. gr. i. t.d.s. as superior to intramuscular injections. For ordinary cases of early infection he gives three intravenous injections of 0·9 g. of neosalvarsan at intervals of three weeks, and mercury by the mouth; at the end of six months a W.R. is performed, and, if negative, the mercury is continued to the end of the year, when a further test is done. If at either of these two examinations the reaction shows signs of becoming positive, a further course of three injections of neosalvarsan is given. At the end of the year of treatment, if the reaction is negative all treatment is stopped, and the blood is examined at three-monthly intervals. If it remains *clearly* negative a year after treatment has been stopped, the patient is dismissed as cured, but further examinations of the blood are recommended from time to time, and the cerebro-spinal fluid is also tested. We have described this method in detail because it differs materially from that employed by most syphilologists. It is so simple that, if Dr. Whitfield's claims for it are justified, it might well be adopted as a standard method in venereal clinics with much saving of time and trouble.

The descriptions of the tumours of the skin are brief but excellent; we observe that Dr. Whitfield disagrees with Mr. Sampson Handley's view that in Paget's disease of the nipple the epidermal changes are secondary to lymphatic obstruction dependent on malignant infiltration of the underlying tissues. Mycosis fungoides is classed as a primarily malignant disease, and not as an infective granuloma, owing to "the richness in mitosis of the new cellular collections."

In the next edition it is to be hoped that the author will include descriptions of certain diseases of which no mention is made in the present one, even though this may involve an increase in size of the volume. Thus pruritus ani and vulvæ are not considered at all, and we can find no reference to granuloma annulare, the sarcoids, and granulosis rubra nasi. On the other hand, conditions such as chigœ disease, myiasis, cysticercus cellulosæ, glanders, and blastomycosis, which are hardly ever met with in this country, might well be omitted. The illustrations are admirably produced.

JOURNALS.

The Journal of Biological Chemistry (Vol. XLV., 1920–21) contains useful contributions on various problems of nutrition, of which the following may be specially mentioned:—

Relation of Fodder to the Antiscorbutic Potency and Salt Content of Milk (p. 228), by A. E. Hess, L. J. Unger, and G. C. Supplee.—Feeding experiments on guinea-pigs with the milk of pasture-fed cows and cows fed on a dry fodder (antiscorbutic-free) diet, showed that with the milk of the latter all the guinea-pigs developed scurvy within 21 days and died within 56 days, whereas with the pasture-fed milk the guinea-pigs were still alive after 120 days, two only showing mild signs of scurvy. Chemical analysis of the milk showed that pasture-fed samples had a higher calcium, phosphorus, and citric acid content, and although the percentage of protein was slightly greater than in the dry fodder milk, the sulphur content was lower.

The Influence of Diet of the Cow upon the Nutritive and Antiscorbutic Properties of Cow's Milk (p. 119), by A. A. Dutcher, C. H. Eckles, C. D. Dahle, S. W. Mead, and O. G. Shaefer.—Two cows were placed upon a diet poor in vitamine content in the middle of January, and their mixed milk fed in varying quantities to several groups of guinea-pigs. Beginning June 1st, the cows were given a diet rich in vitamine and the feeding experiments repeated. From the data obtained it was concluded that the vitamine content of cow's milk is dependent upon the vitamine content of the ration ingested by the cow. 20 c.cm. of summer milk were superior in nutritive value and in antiscorbutic potency to 60 c.cm. of winter milk. There is a tendency for the milk to become slowly poor in vitamine content when the diet of the cow is low in vitamine, but with a ration rich in vitamine diet the milk becomes of higher nutritive value almost immediately. (For this subject see also Hart, Steenbock, and Ellis, *Jour. Biol. Chem.*, 1920, xlii., 383, and Barnes and Hume, THE LANCET, 1919, ii., 323.)

Studies on Experimental Rickets: I. The Production of Rachitis and Similar Diseases in the Rat by Deficient Diets (p. 333); II. The Effect of Cod-liver Oil Administered to Rats with Experimental Rickets (p. 343), by E. V. McCollum, N. Simmonds, H. T. Parsons, P. G. Shipley, and E. A. Park.—I. This preliminary communication deals with feeding experiments with various faulty diets. Administration of some of these diets to young rats results in the development of pathological changes in the osseous system which are identical with those found in the bones of rachitic children. Each of the diets described produces in young rats disturbances in the growth and formation of the skeleton. The large variety of dietary formulæ, the administration of which results in rickets and kindred affections, gives abundant evidence of the complex nature of the causes operating in the production of the disease and their analysis will form the subject of later papers. II. Preliminary experiments afford conclusive evidence of the specific beneficial effect of cod-liver oil on rats suffering with experimental rachitis, in that some substance or substances in the oil will cause calcium to be deposited in the same fashion in which deposition occurs in spontaneous healing of rachitis in man. They also prepare the way for the elaboration of a test for the determination of the calcium-depositing potentiality of any substances in terms of cod-liver oil units.

Growth on Diets Poor in True Fats (p. 145), by T. B. Osborne and L. B. Mendel.—Work on the rôle of fats in nutrition is reviewed and the results given of feeding experiments on young rats, with diets presumably containing adequate amounts of both fat-soluble and water-soluble vitamines, but exceedingly poor in true fats (i.e., compounds soluble in pure ether). The authors conclude that if true fats are essential for nutrition during growth the minimum necessary must be exceedingly small.

The Comparative Effects of Thyroid and Iodide Feeding on Growth in White Rats and in Rabbits (p. 69), by A. T. Cameron and J. Carmichael.—Continued small doses of desiccated thyroid gland fed to young white rats produce (*a*) a definite and invariable decrease in growth rate; (*b*) hypertrophy of the organs concerned with increased metabolism—heart, liver, kidneys, adrenals, &c.; (*c*) disappearance of fat (confirmatory of Hoskins and Herring). The decrease in rate of growth is proportional to (*a*) the amount of thyroid fed and (*b*) the iodine content of the thyroid fed: the hypertrophy varies with dose and length of application of dose, and appears to be proportional to the iodine content of the dose. Sodium iodide fed in quantities varying from amounts equal in iodine value to the thyroid doses to amounts 100 times as great produces no effect on growth rate and no hypertrophy. Both thyroid and iodide feeding increase the colloid in the thyroid. Thyroid feeding inhibits the growth of the thyroid, but iodide does not produce this effect. Similar results were obtained from thyroid feeding with rabbits.

The Effect of Alkali on the Efficiency of the Water-Soluble Vitamine B (p. 423), by T. B. Osborne and C. S. Leavenworth.—This investigation confirms the observations of those who have reported the destruction of water-soluble vitamine B when heated with alkalies, but it appears that in attempting to concentrate, or isolate, water-soluble vitamine B dilute alkaline solutions can be used without materially affecting its activity provided that a low temperature and a short time of exposure to the alkali are employed.

Comparative Metabolism of Proteins of Unlike Composition (p. 289), by W. G. Karr.—From experiments on dogs, as far as is indicated by the urinary nitrogenous end products, the metabolism of two proteins, casein and wheat gluten, widely differing in their chemical composition, is essentially the same. In metabolism experiments with comparable quantities of yeast as the sole source of protein, the partition of urinary nitrogen compared favourably with what was observed after feeding with the other two proteins. The utilisation of the yeast nitrogen was about 80 per cent.

Relationship between Cholesterol and Cholesterol Esters in the Blood during their Absorption (p. 255), by A. Knudson.—A series of experiments carried out on dogs, feeding them with cholesterol and cholesterol esters respectively, shows that free cholesterol content of the blood is increased considerably in all experiments during the absorption of the diets, but there is no apparent change in the amount of cholesterol in the ester form.

Other articles deal with quantitative relations of the constituents of various body fluids:—

Determination of Chlorides in Blood (p. 113), by A. S. Whetmore. The Determination of Chlorides in Trichloracetic Acid Filtrates from Whole Blood and Plasma (p. 437), by M. Smith. Simplified Method for the Determination of Chlorides in Blood or Plasma (p. 449), by J. C. Whitehorn. The Determination of Chlorides in Blood Plasma (p. 461), by J. H. Austin and D. O. Van Slyke.—The above papers describe methods in which the removal of blood proteins is carried out with copper hydroxide, trichloracetic acid, tungstic acid, or picric acid, and subsequent estimation of the chloride in the filtrate by the Volhard method or the iodometric method of McLean and Van Slyke. It is concluded that the simultaneous precipitation of blood proteins and silver chlorides is open to error and not advisable. The simplified method form Supplement II. of "A System of Blood Analysis" (Folin) and the thiocyanate titration is made on the protein-free filtrate (tungstic acid precipitation) after addition of standard silver nitrate solution and without removal of the silver chloride precipitate.

The Determination of Sodium in Blood (p. 312), by Edward A. Doisy and Richard D. Bell.—The method of Ball (*Jour. Chem. Soc.*, 1910, xcvii., 1408) depending on the precipitation of sodium as sodium cæsium bismuth nitrite has been elaborated and details are given for the estimation of small quantities of sodium in blood and urine by gravimetric, volumetric, and colorimetric procedure. See also Kramer (*Jour. Biol. Chem.*, 1920, xli., 263) for method of estimation of sodium based upon the insolubility of sodium pyro-antimonate.

Absorption and Elimination of Manganese Ingested as Oxides and Silicates (p. 133), by C. K. Reiman and A. S. Minot.—The analysis of the blood of manganese workers showed no marked variation from the normal manganese content (0·012 mg. per 100 c.cm). Experimental work showed that ores containing manganese as oxides and silicates are soluble in gastric juice; that manganese is absorbed in the blood stream causing a slight temporary rise in manganese concentration followed by a quick return to the normal. In none of the cases studied was the manganese content of the blood increased by the ingestion of manganese ores to a value more than double the normal level, and in some of the subjects no increase was noted. Prolonged feeding of large amounts of manganese ores to dogs failed to produce significant changes in the manganese content of blood and tissues or to cause pathological symptoms. Manganese ores are non-toxic, and in order to produce symptoms of poisoning must be ingested by individuals who are peculiarly susceptible; such individuals are rare.

Gasometric Determination of Nitrogen and its Application to the Estimation of the Non-protein Nitrogen of Blood (p. 223), by R. L. Stehle.—5 or 10 c.cm. of the filtrate obtained from the blood after tungstic acid precipitation are submitted to the usual Kjeldahl digestion, after which decomposition with sodium hypobromite is carried out, and the volume of nitrogen measured. The method is stated to have certain advantages over the Kjeldahl procedure.

The Iodometric Determination of Copper and its Use in Sugar Analysis: (1) Equilibria in the Reaction between Copper Sulphate and Potassium Iodide (p. 349); (2) Methods for the Determination of Reducing Sugars in Blood, Urine, Milk, and Other Solutions (p. 355), by P. A. Shaffer and A. F. Hartmann.—The reversible reaction $Cu^{++} + I^- \rightleftharpoons Cu^+ + I_2$ has been investigated and applied to the determination of the mixture of cuprous and residual cupric copper resulting from the action of reducing sugar upon alkaline copper solutions. The reaction may be caused to take place to completion in either direction, thus enabling the determination by iodometric titration of the cupric or the cuprous copper in a mixture of the two forms. Details of methods for both titrations are given and their application to the determination of reducing sugar in milk, blood, urine, and other solutions.

The Estimation of the Bile Acids (p. 415), by C. L. A. Schmidt and A. E. Dart.—A method is described for the estimation of the nitrogen of bile acids of the taurine and glycocoll series. It is based on the fact that on hydrolysis with NaOH the bile acids are split giving taurine and glycocoll which react quantitatively with HNO_2. The taurine nitrogen can be estimated from the total sulphur-content of the protein-free bile.

A Method for the Determination of Chlorine in Solid Tissues (p. 427), by R. D. Bell and E. A. Doisy.—The method depends on the rapid digestion of the tissue with concentrated sulphuric and persulphuric acid, the digestion gases being carried over by suction into alkaline sulphite solution in which the chlorine is estimated by the Van Slyke-Donleavy method. Details of technique and special apparatus used are given.

Relationship between Plasma Bicarbonate and Urinary Acidity following the Administration of Sodium Bicarbonate (p. 101), by W. J. Palmer, H. Salvesen, and H. Jackson, jun.—In normal and pathological cases following the administration of sodium bicarbonate the plasma bicarbonate CO_2 approaches 68·7 ± 10 volumes per cent. at the time the first depressing effect of the alkali on the urinary acidity is noted. The use of the first significant effect on the pH of the urine, therefore, in controlling the therapeutic use of sodium bicarbonate, is safe and reliable, but owing to the inconstancy of the level of the plasma bicarbonate CO_2 at this point the accurate estimation of the degree of diminished alkali reserve cannot be made. The observation of Palmer and Van Slyke is confirmed that "absorbed sodium bicarbonate is distributed in approximate uniformity...... to the blood"; and "the effect of a given dose in raising the plasma bicarbonate may be calculated by assuming that the body contains 700 c.cm. of fluid per kilo and that the bicarbonate is distributed therein uniformly." On this subject see also Calvert, Myers, and Milroy, *Jour. Path. and Bact.*, xxiv., 91, 1921.

Relation of the Alkali Reserve of the Blood to Glycosuria and Hyperglycæmia in Pancreatic Diabetes (p. 51), by B. M. Hendrix and C. Y. Crouter.—A decrease in the alkali reserve of the blood, as shown by the CO_2 capacity of the plasma, is not simultaneous with the appearance of hyperglycæmia and glycosuria in pancreatectomised dogs. A slight increase in the CO_2 capacity of blood plasma was observed on the first or second day after removal of the pancreas, later decreasing and gradually reaching about 30 volumes per cent. in two cases. Definite acidosis appears comparatively late in pancreatic diabetes in dogs.

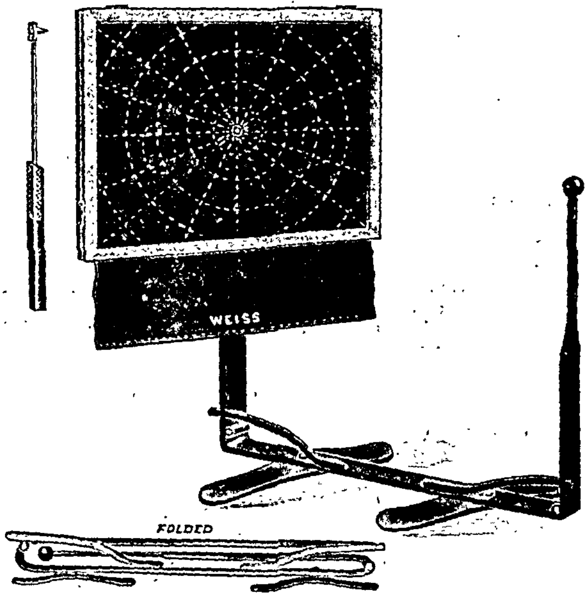
Studies of the Distribution of Carbon Dioxide Between Cells and Plasma (p. 245), by L. W. Smith, J. H. Means, and M. N. Woodwell.—From the investigation of the CO_2 content of the whole blood and plasma of both venous and arterial blood it has been found that as the blood passes from the arterial to the venous side of the circulation in normal man its corpuscles gain from 4 to 11 volumes per cent. of CO_2; the corresponding gain in the plasma is only from 0·0 to 1·8 volumes per cent., and the conclusion is drawn, therefore, that the nsport of CO_2 is accomplished mainly by the corpuscles. The me holds true in anæmia and certain other diseases, although e actual distribution of CO_2 between cells and plasma is ered.

New Inventions.

A DIRECT RECORD SCOTOMETER

FOR INVESTIGATING THE CENTRAL FIELD OF VISION.

VARIOUS instruments have been devised for the purpose of mapping out central fields of vision, but the chief difficulties in this kind of perimetry have been due to the slowness of the means of taking the observations. For the past two years I have been using an instrument which overcomes this difficulty. Observations may be made quickly and accurately, and at the same time a direct record of the observations is taken. The apparatus consists of a rigid iron stand to which is fitted a frame carrying the screen against which the observations are to be made. The screen is of grey cloth, fixed into it in the central position is a small white metal stud; this is the fixation point. Behind the screen is a sheet of carbon and a paper chart, ruled for convenience in the usual degree circles and radii. Red and blue tracing papers are also supplied, which enable three records to be taken, at intervals, on the same chart. The object is carried on a suitable object holder and held in the surgeon's hand, which is obscured from the patient's view by a grey cloth bag-glove. At the back of the frame knobs are fixed in the usual positions of the blind spots, so that the surgeon has a reliable guide from which to work. In taking observations the patient's face at the naso-buccal groove is pressed against the knob on the free upright of the stand. One eye is covered, the other looks at the fixation spot. The surgeon moves the object over those parts of the field he desires and notes when the patient sees it and when he does not. The records of the observations are made by pressing the small stylo on the back of the object holder against the screen, when the impress is conveyed by the carbon sheet to the chart. The whole of the movements of the object over the screen may be traced in this fashion by a light continuous pressure and salient points marked by deeper pressure.



The real advantage of this recording instrument is the speed and accuracy with which observations may be made. If the surgeon has to move about, take notes, shift the instrument, or do anything that takes time or diverts the patient's attention, accuracy of observation is diminished or indeed may be lost entirely.

The instrument has been well made by Messrs. John Weiss and Son, Ltd., of 287, Oxford-street, London, W. 1.

THE LANCET.

LONDON: SATURDAY, APRIL 16, 1921.

Sanatorium Treatment under the County Councils.

ON May 1st next sanatorium benefit under the Insurance Acts ceases to exist and the duty of providing institutional treatment for persons suffering from tuberculosis falls to the county councils. Parliament will be asked to vote a sufficient amount of money to the Ministry of Health to enable grants to be made to the councils equal to the lapsed sanatorium benefit income, and the annual Exchequer grant will make up the amount to one-half of the approved expenditure. A further 50 per cent. grant is to be sanctioned to provide extra nourishment for patients not in residential institutions provided the amount expended for this purpose does not exceed £2 per 1000 of population. Some restiveness is apparent in the House of Commons at the increasing burden on tax- and rate-payers on account of the residential treatment of tuberculosis. It is, perhaps, not an unmixed evil that sanatorium treatment is at present the subject of much criticism. Were its position secure there would be little hope of lifting it out of a stereotyped groove and of remoulding it in conformity with present needs and recent advances in our knowledge of tuberculosis. A curious feature of many criticisms of the results of sanatorium treatment is the total absence of any definition of the term "sanatorium treatment." Yet it is obvious that definition should precede discussion. We must, for example, define the time limit within which residence in a sanatorium is so short that the patient cannot, in common fairness, be said to have enjoyed sanatorium treatment. No one would condemn university education because an undergraduate who left college at the end of his first term proved an illiterate man. But sanatorium treatment is freely condemned in this country because many patients relapse after three months' treatment in a sanatorium. No case of active pulmonary tuberculosis has ever been cured in three months by sanatorium treatment, and no case ever will be. Though it is easy enough to fix the limit within which sanatorium treatment is farcically inadequate, it is a far more difficult task to fix the maximum limit beyond which sanatorium treatment can do no further good; for, as Dr. J. CROCKET[1] has pointed out, a brilliant result achieved by three years' sanatorium treatment would probably have been stultified had this treatment been limited to two years.

Apart from the question of time, there are very divergent views as to what constitutes sanatorium treatment. Wielding a pick and shovel, sleeping in a draught, and imbibing much milk is the order of the day in certain institutions where the comparative amounts of rest and exercise are graduated by the mouth temperature and by such signs of toxæmia as headache and lassitude. In other institutions no exercise but walking is allowed, and then only in carefully graduated doses, auto-inoculation is controlled by the rectal temperature taken many times a day, the warmth and general comfort of each patient are studied, and the physician plays the part of providence in tempering the wind to the shorn lamb. Again, in several sanatoriums an elaborately devised system of heliotherapy has lately been introduced, while in others hydrotherapy plays an important part. Many other methods included under sanatorium treatment could be mentioned, but the diverse systems referred to will suffice to show how varying are the conditions under which patients are put when given "sanatorium treatment." The time may come when sanatorium treatment will be "standardised" by the elimination of comparatively useless or even harmful methods, and by concentrating only on those methods that survive the test of time; and in the meantime our judgment of the results at present achieved should be tempered by the regretful admission that the term "sanatorium treatment" covers a variety of methods of very different value. Another important factor in the problem of sanatorium treatment is the class of case selected for this treatment. In the past the selection of candidates for admission has often been determined by other considerations than those actuating the medical advisers consulted. And, more unfortunate still, it has often happened that advanced and incurable cases have been given long spells of sanatorium treatment at the expense of early cases which are discharged after a few months. A most important step to remedy this state of affairs has lately been taken by the London County Council, the Public Health Committee of which has recommended that all patients should, if possible, be passed through observation beds before being sent to an institution such as a sanatorium. By the reservation of 250 such beds at the Brompton Hospital, and 75 at the City of London Chest Hospital, and by the detention of patients in these beds for two to four weeks, valuable information can be obtained as to the needs of the individual case, and an example is set which will no doubt be followed by other bodies concerned with the welfare of the working-class tuberculous patient. It is a curious fact in the evolution of sanatorium treatment that, while preventoriums and sanatoriums for children often have waiting lists, sanatoriums for adults are sometimes only partly filled, although the sanatorium accommodation available for adults is, in theory, notoriously inadequate. This tendency may, perhaps, be a reflection of the results achieved by the two classes of institution, and we would venture the prophecy that sanatorium treatment will more and more develop on the lines of prevention in the young than "cure" in the adult.

In a recent report[2] five of the leading tuberculosis specialists in Canada have published the results of a tour of inspection of 26 Canadian sanatoriums. Appointed by the Department of Soldiers' Civil Re-establishment, these specialists were given the task of scrutinising all the conditions under which soldiers were treated in sanatoriums and other institutions for the tuberculous. This report dwells on the facts that "the vast majority of patients are treated for too brief a time," and that the "medical service of most sanatoria was relatively under-staffed." Some, indeed most institutions were run as well as circumstances permitted, but in others "inadequate medical supervision was responsible for an atmosphere of depression ......" Many other pertinent observations are made, the shady as well as the sunny side of sanatorium administration being shown up in true relations. This searching survey and candid discussion will provoke in those concerned with sanatorium treatment a divine discontent with all that is make-shift and second-rate. Such a tour of inspection in this country, if it were made by a body of experts with many years of sanatorium experience, would, no doubt, ultimately do much to raise the standard of sanatorium treatment. Already there are certain influences at work which should help to promote efficiency in the sanatorium service. Under Dr. JANE WALKER'S vigorous direction the Society of Superintendents of Tuberculosis Institutions has become a vocal body which, to judge by the reports of its various subcommittees just issued, is animated by the ambition to set its house in order. A tell-tale book with the title of "Anti-Tuberculosis Reconstruction,"[3] by an author who designates himself D.P.H., R.C.P.S.I., shows an almost uncanny knowledge of the seamy side of the sanatorium service, and the proposals for the betterment of the tuberculosis service of the country are evidently the offspring of long and varied experience. These and similar influences augur well for the future. At present, however, the position is obscured by conflicting evidence; on the one hand, Dr. E. WARD[4] thinks that the calculation that two out of 10 early cases are cured or materially relieved by sanatorium treatment is too optimistic; and, on the other hand, Professor SAUGMAN[5] has shown that complete and permanent recovery can be effected by sanatorium treatment in eight to nine out of every 10 cases of early pulmonary tuberculosis.

Income-Tax.

THE new Revenue Bill just introduced, separately from the annual Finance Bill, contains provisions regarding income-tax to which members of the medical profession will, sooner or later, require to attend personally or by deputy. If the profession is nowhere specifically mentioned in the Bill, there are many provisions in which incomes of the average professional sort are concerned. The Bill, indeed, contains only one clause which relates to other than commercial or professional aspects. By that clause power is given to the taxpayer to require the Bank of England to deduct tax from interest on dividends on War Loan and other Government securities which would otherwise in ordinary course be payable without deduction of tax at the source. Presumably some desire must have been manifested for this discretion, but we cannot say that we are impressed with its advantage as against allowing the tax to be directly assessed. However, the power is there, and no doubt there are cases where it may be useful. With this exception the Bill contains nothing that can be described as of a domestic nature. There is no change in the family allowances, and the subject of wear and tear is never mentioned. In an obvious direction this is of importance to our readers, for it leaves the medical profession where it is as regards any allowance for cars. There can be no account taken of wear and tear—in other words, there is no allowance for depreciation. But all repairs are chargeable, and can be brought into account for remission of tax; also renewals where one car is exchanged for or replaced by another will be allowed for, less the salvage of the old car.

These matters concern a section of the medical profession; but all will be affected by the new basis of assessment. Public appointments are to remain chargeable on the figure of the year of assessment. But ordinary professional profits are to be placed on a new basis, beginning with the tax year 1922–23—that is, one year hence. The basis is at present the average of the three preceding years, but in the following year the basis will be altered to the figures of the year preceding. Thus in 1922–23 the tax will be charged on assumed profits equal to the actual ascertained profits of the last professional financial year, according to the date on which the accounts of the practice are usually closed. That, for instance, may be the present calendar year 1921. The rules will remain the same as at present, but there are important new regulations applicable to new practices, discontinued practices, successions in practice, and partnership changes. These matters are too involved to be gone into here. To mention their existence is to justify the advice that the medical man should study all the directions closely, and should not be reluctant to call in expert aid. He may often need it.

There is one thing to which attention ought to be distinctly directed, and that is the possibility of hardship on changing over from the one assessment basis to the other. Thus, suppose the accounts of the practice are made up annually at Dec. 31st. If the present system of the three years' average continued in force, the 1922–23 assessment would be on the average of the years ending Dec. 31st, 1919, 1920, and 1921. But under the new basis the standard will be the 1921 profits only, and it may easily turn out that those are materially higher than the average of 1919–1921. If so, there may be a remedy; but it will be hopeless, it seems to us, to expect to obtain it if there are not accounts in existence for a good many years back. There is no remedy unless the practitioner can prove that the profits of 1919 *or* 1920 were less than the average of the six years preceding 1919 (1913–1918). If this can be proved then the practitioner will be entitled to claim that the assessments of 1922–23 and 1923–24 shall be made on the present three years' average basis. In that case the assessment for 1922–23 would be on the average of 1919–20–21, and that for 1923–24 on the average of 1920–21–22. That would be the end of the exceptional transition relief, and the assessment for 1924–25 would be on the profit of 1923.

Hypno-Narcosis.

GREAT discoveries seem to bide their time and to appear when due almost irrespective of human agency. Otherwise it would be difficult to explain how DARWIN and WALLACE came to propound independently the principle of evolution, why Neptune was discovered simultaneously in two observatories, or whence exophthalmic *goitre* derives its three eponyms. So it was that painless operating emerged during the eighteen-forties in four several places, and with a different method in each. The tale of nitrous oxide (1844), of ether (1846), and of chloroform (1847) has often been told, but it is not so often recalled that in 1845 James Esdaile, at the Native Hospital, Hooghly, performed the first painless operation under what was then known as mesmeric influence. Before he left India in 1851 he claimed to have performed thousands of painless minor operations and some 300 capital ones. James Braid, surgeon, of Manchester (1795–1860), to whom we owe the term hypnotism, did not himself use it as an analgesic for other than dental extractions and small surgical interferences such as the opening of an abscess. Hypnosis as an analgesic could hardly expect to get a fair hearing in a world newly impressed by the magic powers and apparently simple technique of ether and chloroform. To the *Deutsche Revue* of March Professor A. A. Friedländer, of Freiburg-i-B., contributes an interesting article on the psychology of hypnosis and its relation to surgery, in which he goes over with striking fairness some of this old ground. He points out of what inestimable value for suffering humanity were the experiments of Braid and Esdaile, and how they were rendered nugatory by the rapid popularisation of narcotic drugs. From his own experience of hypnotic phenomena Professor Friedländer became convinced that hypnosis could be enlisted to aid surgery in a fashion quite different from that in which Braid had used it. From 1905 on he was led to treat patients by hypnotic suggestion before and during operation, calling this combination of hypnosis with narcosis hypno-narcosis.

---

[3] Maunsel and Co., Ltd., pp. 33, 6d.

[4] THE LANCET, March 12th, 1921.

Meddelelser fra Vejlefjord Sanatorium, 1920. G. E. C. Gad, Copenhagen.

The advantages of hypno-narcosis in its author's hands are these. Light hypnosis induced before an operation will establish the patient's equanimity and prevent the natural anxiety associated with the operation and with the taking of an anæsthetic. The principal induction takes place just before the operation, the patient then being slowly anæsthetised so that the narcotic state supervenes upon the hypnotic. Narcosis ceases as soon as the operation is completed and hypnosis is again brought into use. The benefits are immediate. The amount of narcotic used is reduced by one-third, or two-fifths of what would otherwise be required. Any toxic action is, therefore, of the slightest, after-effects being correspondingly reduced. The patient awakes from a sleep rather than from a narcosis. A similar treatment may be employed in childbirth, the patient being fortified by preliminary suggestion. The small consumption of the anæsthetic is specially important in Germany in view of the present high cost of chemical products. Hypnotic after-treatment is directed to securing rest and sleep. In this way secondary hæmorrhage is avoided, and the recourse to sleep-inducing drugs. Prolonged hypnotic sleep extended over hours, or even days, renders possible any special treatment of the patient, forced feeding, and the establishment of physical and mental repose. All this without any alteration of the surgical department other than the addition of an assistant instructed in psychotherapy, for skill in inducing hypnosis is all-important. Professor Friedländer sees a great future for hypno-narcosis. It is destined, he thinks, to become the common property of practising physicians, and to play the part in therapy that anatomy accomplishes for surgery. Without supporting him all along these diverging lines we may say that he makes out a good case for extended trial of hypno-narcosis.

Annotations.

"Ne quid nimis."

THE NECESSITY OF REGISTRATION.

In view of the recent legislation and prospective regulations, medical practitioners are reminded that no matter what qualifications may be possessed, a man is not "legally qualified" or "duly qualified" unless he is registered; and that the Medical Register is alone evidence upon this point "until the contrary be made to appear." For those who specially require them, lists are prepared each month giving the names of all those registered during the month, and also of those who have died or whose names have been removed from the Register for any other reason. All communications should be addressed to the Registrar, General Medical Council, 44, Hallam-street, London, W. 1.

THE RÔLE OF PREFORMED CARBOHYDRATES IN NUTRITION.

The interesting question whether preformed carbohydrate in the diet is required for growth has recently been raised by T. B. Osborne and Lafayette B. Mendel, of Yale University, in the number of the *Journal of Biological Chemistry* reviewed in our present issue. Their results would seem to show that even what are now considered established principles in dietetics may require revision, for carbohydrates are ordinarily regarded as indispensable components of the food intake. This belief is based on the presence of more or less carbohydrate in the food mixtures consumed by the higher animals and man and on the fact that sugar is a constant constituent of the blood. Some observations connected with diabetes seem to confirm this view; since ketone substances may be excreted in diabetes when sugar fails to be burned up in the normal manner, it would seem that carbohydrates are essential for the proper metabolism of the fats. It is known, however, that meat contains very little carbohydrate; yet purely carnivorous animals grow and maintain health on a practically pure animal diet. What can then be said about omnivorous vertebrates? Rats were fed successfully on rations which included protein—casein, edestin, or lean beef which had been thoroughly extracted with boiling water—inorganic salts, agar-agar, lard, butter-fat, and 0·4 g. daily of dried brewery yeast furnishing vitamin B. The yeast can scarcely be regarded as a significant source of available carbohydrate. Success was likewise attained in experiments in which no agar-agar was given. In these experiments the only obvious sources of preformed carbohydrates were the yeast employed and such carbohydrate impurities as might still adhere to the protein preparation in the dietary. Osborne and Mendel, as the result of their experiments, found that rats receiving a diet in which the amount of carbohydrate was at most exceedingly small can grow from an early age to adult size.

TOWN SCHOOL HYGIENE.

> "It would pay local authorities to scrap all school buildings in the centre of the cities and to build on the outskirts, where the winds blow, the flowers grow, and the birds sing."

This ideal was set by Mr. C. T. Wing, the representative speaker at the recent conference of the National Union of Teachers at Bridlington. It is in essence a plea for rural life and the open-air school, natural enough at a holiday conference on the bracing East Coast, but it may be doubted whether the proposal would justify itself economically. The borough of Poplar has recently demanded the rebuilding of its schools, but Dr. Leonard Hill has shown that if overheated air is avoided and constant movement of air ensured, healthy physical conditions of atmosphere can be obtained in the centre of a town as well as in the country. Rural and urban schools evidently share the same disadvantages to a large extent. Many village schools are insanitary. Much of the trouble arises from the control of the schools being much in the hands of a section of the community other than that which uses them. If every child in the country, irrespective of the amount of income his father earns, had to put in five years in an elementary school, that school would be a different place. Knowledge of school hygiene is still ahead of its practice. Teachers appear to be moving forward to take their place as professional workers, but they have still to realise as a whole that they must teach for physical as well as mental results. Over and over again, before the school doctor came on the scene, teachers were shown how filthy were the heads of school children, a fact which hardly needed the elaborate statistical analysis given to it in official reports. The plea raised by speakers at the same conference that teachers should attempt to improve their status would be greatly strengthened if they determined to add to their equipment a competent knowledge of the physical conditions requisite for the growth and development of their charges. Hitherto this side of the teachers' work has needed continual impressing upon them by outsiders. Cleanliness, neatness, tidiness, and a joyous outlook on life are requisites whose importance is urgent in these days when the basic value of Freud's discovery is emerging from the slime with which it has been surrounded. The all-powerful effect on the juvenile mind of suggestions of healthy ways and means cannot safely be neglected by any teacher, for one-ninth of a child's life during educational years is passed in school. Still, it is only a ninth, and the slum in which the remaining eight-ninths is spent will pay better for improvement than will the removal of schools to the suburbs.

A FATAL PRACTICAL JOKE: PNEUMATIC RUPTURE OF THE INTESTINE.

DR. J. R. Buchbinder has reported a fatal form of joke which has been practised in America for some years—we have ourselves reported instances of its occurrence. A man was admitted to the Wesley Memorial Hospital, Chicago, with the history that two hours before, while stooping, a fellow-workman had placed the nozzle of an air hose close to his rectum. The nozzle had an inside diameter of 1¼ inches, and delivered air at a pressure of 85 lb. The man screamed with pain and collapsed. On admission he was in a state of profound shock. His face was slightly cyanosed and respiration was scarcely noticeable. While being lifted into bed, and thereafter until removal to the operating-room, he was seized with violent clonic spasms of the trunk. The heart was scarcely audible. The abdomen was greatly distended, but the distension was different from that of peritonitis; the tension was so great that the palpating hand could hardly make an impression. The abdomen was not merely rigid; it was extremely hard. The skin of the chest, abdomen, scrotum, penis, and perineum was emphysematous. Under procaine anæsthesia a left rectus incision was made. The transversalis fascia was not incised, but sharp-nosed forceps were pushed through in order to control the escape of air. The fascia tore like wet paper under great tension, the air rushed out with a report, and the abdominal wall dropped in. The sudden escape of air proved nearly fatal, but in a few minutes the patient rallied. There was a tear in the convexity of the sigmoid, which admitted three fingers. For a distance of 6–8 inches the serosa was stripped off and ribboned. The colon was collapsed and practically empty. The mucosa had herniated through the tear in the serosa and was frayed out as though it had been scraped. The meso-sigmoid was studded with small hæmorrhages, but there was little blood and no fæces in the peritoneum. The sigmoid tear was closed and the peritoneum sutured as well as it could be with what was left of it. A loop of descending colon was pulled out for colostomy. The patient was urned to bed and treated for shock, but died hout fully recovering from it four hours later. necropsy showed that the anus and rectum had escaped injury, probably because of pelvic support. The colon, from the sigmoid to the splenic flexure had become gangrenous, which was attributed to destruction of its blood-supply by the impact of air. The remainder of the intestinal tract showed no injuries. In *Surgery, Gynecology, and Obstetrics* for January, 1911, E. W. Andrews collected 15 cases[1] of this injury, of which 13 were fatal, and reported one in which the damage of the sigmoid was so great that he performed lateral anastomosis and the patient recovered. In the same journal for January, 1914, Bendixen and Blything reported a case in which operation was successful and added six more cases. The combined statistics give a mortality of 81 per cent. in cases in which operation was performed. When no operation was performed the mortality was over 90 per cent. In most of the cases the anus and rectum escaped injury. In nearly every case the sigmoid was the site of injury probably because its loop and kinked junction with the descending colon offers obstruction to the rush of air. The peritoneal coat was torn to ribbons and the mucosa protruded. Dr. Buchbinder recommends that the intraperitoneal pressure should be immediately relieved, allowing the air to escape slowly, preferably by a rectal tube, and then that laparotomy be performed under local anæsthesia for repair of the ruptured bowel. Colostomy should be considered when there is extensive destruction at the site of rupture or when the blood-supply of a considerable length of colon is compromised.

MILITARY AMBULANCE TRAINS.

QUICK transport for wounded and sick of the armies from the battle line to the base hospitals came to be of far greater importance in the late war than in previous wars. The large numbers of slightly wounded and sick who were quickly cured with proper treatment away from the front, and so able to resume their active parts in the war within a reasonable space of time must have formed important items in the military use of man-power. There was also the humanitarian consideration. Swift and comfortable transport saved many lives and an almost incredible amount of suffering. From the point of view of medical administration, there was also the enormous relief given to casualty clearing stations. During a heavy engagement thousands of wounded would be collected at a C.C.S., many more than the available accommodation would hold, and many more than the medical and nursing staff could cope with, even working 24 hours a day. By the use of ambulance trains it was possible to keep selected and urgent cases at the clearing stations, and yet be sure that the remainder would immediately get food and medical attention, and that within a few hours they would be right away from the battle zone at base hospitals. An instructive chapter in Mr. E. A. Pratt's book "British Railways and the Great War," tells us of the development and organisation of ambulance trains. Mr. Pratt points out that the experience of the South African campaign had been embodied in plans drawn up before the outbreak of the late war for immediate expansion of the ambulance-train service. Five ambulance coaches were used constantly from 1900 onwards by the L. and S. W. Railway to transfer sick troops arriving at Southampton from India and elsewhere to inland hospitals. These were expanded to 30 fully equipped hospital trains for overseas ambulance work. Further, by the end of the war 19 trains had also been provided for the United States Army, bringing the total of overseas ambulance trains supplied by the railways to 49. Moreover, some 24 of these trains were organised for service in England. This work was carried out by committees chosen from general managers and superintendents of the railways, the military organisation being under Sir William Donovan and his staff. The story is one of ever-increasing demands for trains and also of steady improvement in their standardisation. A typical train was composed of 16 vehicles—viz., one combined brake-car for lying infectious cases, one staff car, one kitchen and sitting officers' car, nine ordinary lying ward-cars, one pharmacy car, one kitchen and mess car, one car for personnel, and one brake and stores car—accommodating lying cases 320, sitting 76 (at least), staff 8, personnel 39—total 443. Each new train conformed to this general standard, but each had its improvements. To develop an organisation to supply all the ambulance trains overseas and for the extremely wide distribution of patients in Great Britain was no light undertaking. Arrangements were made to send the patients who were entrained chiefly at Dover and Southampton to hospitals which had sprung up in all parts of the country, and an extremely complicated system had to be evolved to enable the authorities to know how many beds were vacant in all and in each of these hospitals, what class of cases they took, and how best to divide, say, a shipload of 500 patients amongst these various institutions, and avoid waste of mileage and of beds. Combined with this work were the transfers from hospital to hospital in the United Kingdom, designed to place patients nearer their own homes or in special hospitals From the outbreak of war until April 7th, 1919, the total number of sick and wounded received into ports in the United Kingdom and conveyed therefrom in ambulance trains was 2,680,000. These were distributed all over the country to 196 receiving stations, trains going as far north as Aberdeen. Mr. Pratt closes his excellent account with a short summary of the ambulance work done by railwaymen.

THE TRANSMISSION OF KALA-AZAR.

THIS very fatal disease has long presented difficulties to investigators desirous of discovering the methods of its transmission. Its specific organism, the Leishman-Donovan body (*Leishmania donovani*), is a protozoon which is stated to pass through three stages of development (pre-flagellate, flagellate, and post-flagellate). The chief endemic area of kala-azar is at present in Assam, where, according to recent reports, an increased incidence has been observed during the last three or four years. Formerly the case mortality-rate of kala-azar in Assam was at times as high as 98 per cent., but a reduction has lately been effected by the treatment of cases by the intravenous injection of tartar emetic. The ætiologist has been anxiously striving to find out how kala-azar is spread so that appropriate measures might be formulated for preventing its diffusion, but as yet without much success. In the *Indian Journal of Medical Research*, Vol. VIII., No. 1, Captain R. Knowles, I.M.S., of the Pasteur Institute, Shillong, Assam, has published a series of "Studies of Kala-azar," in one of which he deals with some of the possible methods by which the disease may be transmitted. The occurrence of direct fæcal transmission from person to person by contamination of hands, bedding, clothing, &c., is quite possible, for dysenteric symptoms are generally present in kala-azar cases throughout the course of the disease, and the bedridden, dying patient commonly contaminates, by his bowel discharges, his clothes, and bedding, as well as the floor of the house and the furniture. It is known that the natural intestinal flagellates of insects are transmitted from insect to insect in encysted form through the fæces. It is certain that in man *L. donovani* is passed from the ulcers of the intestinal mucosa into the fæces. So that if the infection is transmitted by means of fæcal contamination, the parasite should be present in the stools in some encysted or resistant form not yet discovered. In the careful investigations conducted by Captain Knowles at Shillong, however, no positive results were reached to support the above views; nevertheless, he concludes that this possibility deserves more careful consideration than it has hitherto received from investigators. It is also worth noting that in Assam, at least, the distribution and incidence of kala-azar is closely associated with insanitary conditions and with an absence of proper provision for excrement disposal.

The almost universal prevalence of hookworm disease in Assam has led to the suggestion that perhaps the ankylostoma may act as a carrier of the kala-azar infection to man. To test this suggestion Captain Knowles carried out a series of careful experiments extending over a period of two and a half years; but he failed to obtain any results in support of it. The hookworm may possibly be a secondary host of the kala-azar parasite, but there is no experimental evidence at present in favour of the suggestion. For some years, and especially after the work of Patton was published, it was believed that the Indian bed-bug was the transmitting agent of kala-azar. More recently other ecto-parasites have also been suspected, including pediculi and acarinæ. The position as regards the relation of the Indian bed-bug and kala-azar seems at present to be that either the bug is the true secondary host, and the infection passes by salivary infection, or, on the other hand, that there is so close an approximation to a true cyclical development of the *L. donovani* in the bed-bug that the true cycle may occur, not in the bed-bug itself but in some other blood-sucking insect. Captain Knowles points out that the flagellate body is almost certainly a part of the extra-human cycle of the parasite, otherwise, he asks, why it should develop uniformly in both culture medium and the mid-gut of the bug. On the other hand, serological work, and the great difficulty met with in attempts to infect animals experimentally with flagellate cultures, seem to indicate that the flagellate body is not the final stage of the parasite infective to man. The form of *L. donovani* infective to man is probably some post-flagellate stage of development of the organism. The experimental investigation of kala-azar is greatly hindered by the want of an animal which can easily and certainly be infected under experimental conditions. The incidence of the disease among Europeans in Assam has so far been limited to males, and the suspected channels of infection seem to be confined to ecto-parasites, such as the bed-bug, louse, or acarus, or to be the result of infection possibly acquired elsewhere, as, for instance, through infected ankylostoma larvæ on the tea-garden soil getting into the human body through leaky or damp boots. The incidence of kala-azar in young children negatives the suggestion that coitus is the usual mode of spreading the disease. Lastly, Captain Knowles states that, whatever the true ætiology of kala-azar may be, three factors seem essentially concerned in its spread—namely, close personal contact, site infection, and repeated or prolonged exposure to the infecting agent. Proof that there existed some extra-human reservoir of the infection in some animal, amphibian, reptile, or fish, would explain several of the most puzzling features of the epidemiology, its occasional latency on the one hand, and on the other the existence of areas so saturated with the infection that every living person in them becomes infected sooner or later. Captain Knowles's investigations, we are glad to learn, are being continued.

LONDON AND COUNTIES MEDICAL PROTECTION SOCIETY.

THE annual general meeting of this society was held at 32, Craven-street, London, on Wednesday, April 6th, the President, Sir John Rose Bradford, in the chair. Sir John Rose Bradford, in proposing the reception of the annual report and balance-sheet, pointed out that the number of members added to the society during the year had been very considerable, while the strength of their organisation was proved by the fact that, unlike so many other associations, their annual subscription had remained unaltered. Dr. C. M. Fegen, the honorary treasurer, in seconding the motion from the chair, stated that a reserve fund of £30,000 had been banked up by the Society, the expenditure had been carefully guarded, and that the value of their securities had been written down as lately as last December, so that the members might not be deluded into thinking that their very good position was a better one still. Dr. C. O. Hawthorne moved an amendment approving of the annual report but asking that the Council should reconsider a decision to send representatives to the Federation of Medical and Allied Societies. He took up no legal standpoint, but submitted that the money paid by the members of the Society was intended for particular purposes in which the pursuit of a medico-political policy was not included. The amendment having been duly seconded, the policy of the Society in subscribing to the Federation was defended by Dr. Fegen, who pointed out that the value of being affiliated to the Federation would be that sympathetic hearing could be secured from Governments, which could not pass over joint representations as they could those of individual groups. Two members only having voted in favour of the amendment the original motion, that the report and balance-sheet be adopted, was put and carried *nemine contradicente*. The meeting ended with the re-election of Sir John Rose Bradford as President, Dr. Fegen as treasurer, Mr. A. G. R. Foulerton as financial secretary, and Dr. Hugh Woods as general secretary, and all the appointments were received by the meeting with great cordiality.

AN ECHO OF THE WAINWRIGHT MURDER CASE.

Mr. F. G. Larkin, who was one of the chief medical witnesses in the Wainwright case 45 years ago, has presented to the medico-legal collection of the Royal College of Surgeons of England the uterus and neighbouring pelvic parts of Harriet Lane—Henry Wainwright's victim. The evidence relating to this case is very clearly given by the late Mr. H. B. Irving in the Notable Trial Series. It will be remembered that Wainwright placed the dead body of his victim under the floor of his workroom, where it lay, surrounded by quicklime, for the greater part of a year. Yet at the end of this time Mr. Larkin was able to recognise that the body was that of a woman who had probably borne children. The identification of Harriet Lane was made, however, on other grounds. And this was fortunate, for at the Obstetrical Society Dr. Alfred Meadows read a note of the evidence which he gave at Wainwright's trial, in which he pointed out that the organ presented appearances not believed to exist in a uterus which has been gravid.

THE "HÉMOCLASIQUE" CRISIS.

IN a recent communication P. Brodin and Charles Richet[1] use this term to describe the circulatory changes which occur in anaphylactic shock, or which follow the intravenous injection of peptone. These changes, most of which have been noted by other observers, are the following: fall of blood pressure, delay in the coagulation of the blood, concentration, leucopenia, and, finally, changes in the viscosity and refractive index of the serum. These occur in both conditions, but in anaphylactic shock there are two additional phenomena—i.e., the appearance of nucleated red corpuscles and a change in the normal differential leucocyte count. Biedl and Krauss some years ago drew attention to the resemblance between the respiratory symptoms and the pulmonary lesions in these two conditions, and Brodin and Richet now present the additional evidence of the similarity of their "hémoclasique" crises, as proof, if not of their absolute identity, at least of the very close relationship between them. There can be little doubt that in the dog such a close resemblance exists between peptone poisoning and anaphylactic shock, for in this animal the point of attack is, in both cases, the endothelial lining of the capillaries. In the guinea-pig, however, anaphylactic death is due to the asphyxia which follows the contraction of the plain muscle of the bronchioles, and though peptone in sufficient dose also produces such contraction of the bronchial musculature with acute asphyxial death, it can cause subacute death in smaller doses by its action as an endothelial poison. No superficial resemblance between the blood changes in these two conditions can obliterate the essential difference in poisonous action of peptone in the normal, and the specific antigen in the sensitised animal, the former functioning as a general endothelial poison, and the latter, as Dale and Weil have shown, following the union of specific antibody with antigen within the body cells. More important are the experiments in "crossed immunity" which Brodin and Richet report. A series of 13 dogs were sensitised by a preliminary injection of horse serum. One or two months later seven of these were given large doses of horse serum intravenously, with the result that one died of acute anaphylaxis, and three others showed severe symptoms. The remaining six dogs were given an intravenous injection of peptone one hour before they received the "déchaînante" injection of horse serum, which in this case caused no symptoms in one dog and only slight effects in the others. This experiment affords some evidence that peptone administered to the sensitised animal affords a partial protection against the subsequent injection of the specific antigen. The dose of peptone used was rather large, 0·1 to 0·15 g. per kilo of body weight, about half the dose necessary to render the blood of a dog incoagulable. This fact renders the experiments inconclusive in regard to the possible value of intravenous peptone injections as a prophylactic measure against anaphylactic shock in man.

THE MANUFACTURE OF AERATED WATER AS A DANGEROUS INDUSTRY.

DRAFT Regulations have been circulated by the Home Secretary, under the powers given by Section 79 of the Factory and Workshop Act, 1901, which it is proposed to substitute for the Special Rules at present in force for the protection of workers in mineral water manufactories. The dangers which beset such workers arise entirely from the bursting of bottles or syphons in the various processes to which they are submitted, and all the regulations are framed with a view to such bursting, except one which orders the provision of waterproof aprons and boots or clogs for persons working in processes which involve exposure to wet. Such changes as are made in the draft regulations as compared with the Special Rules, framed in 1898, are due to the changes in the system of manufacture since that date. For example, the wearing of face guards and gauntlets is no longer imposed upon all bottlers, because automatic filling machines now in general use prevent the escape of the fragments of a burst bottle.

WOUND OF THE KNEE-JOINT TREATED BY CLOSURE AND IMMEDIATE ACTIVE MOVEMENT.

WE described some time ago[1] an advance made during the war by Dr. C. Willems, a Belgian surgeon, who treated acute arthritis, principally of the knee, due to infected bullet wounds, by incision and drainage, followed by immediate active movement, with remarkable success. Although this treatment is contrary to the current teaching its rationale is simple: the movement expels pus and prevents adhesions. In the *Boston Medical and Surgical Journal* of Feb. 17th Dr. L. Allen has reported a case of lacerated wound of the knee-joint in a child which he treated in this manner. A boy, aged 5 years, fell on a broken bottle embedded in the ice, making a jagged cut about 3 inches long to the outer side of the patella, which opened the joint. He was 40 miles away, and his medical attendant telephoned that he was bringing him to hospital, and asking what should be done for first aid. Dr. Allen told him to paint the wound and its neighbourhood with tincture of iodine, and put on a sterile dressing. About five hours after the accident he enlarged the wound under ether, picked out all clots, trimmed all the edges and washed out the joint with 2 per cent. boric acid solution, using several quarts, and keeping his fingers out of the wound entirely. He closed the synovial wound with No. 00 interrupted catgut, sutured the capsule with interrupted No. 2 chromic catgut and kangaroo tendon, closed the skin wound with No. 00 catgut and continuous silkworm-gut and a few interrupted silkworm sutures, carried a small cigarette drain down to the capsule, and painted with tincture of iodine. Light sterile dressings were put on with the knee flexed and then extended so that movements could be kept up. The nurses were instructed to make the child flex and extend his knee to the full extent every two hours day and night, and to use passive movement if he refused. At first the child was afraid to move his knee, but he soon found that it was not painful, and a game was invented which encouraged him to do it. Healing took place by first intention. The drain was removed on the third day, and the sutures on the ninth and tenth days. The child was in bed eight days, and went home on the twelfth day. A report nine months after the accident shows that the joint is quite normal. This case is in strong contrast to one treated by Dr. Allen a short time before by the ordinary method. A young man had a bullet wound of the knee-joint. The treatment consisted in removing the bullet, débridement, drainage, and splint. He died from a streptococcic infection. The contrast is maintained on turning to Willems's results. In 100 cases, of which 18 were accompanied by purulent synovitis of a virulent type, chiefly streptococcic, he had no deaths and no amputations. There was one resection and only two stiff joints.

FOOD AND THE PEOPLE.

A RECENT question addressed to Dr. Addison in the House of Commons asking what steps he was taking to alter war-time food substitutes, in view of their effect on the physique of the worker and his children, elicited the reply that substitutes such as margarine had generally been adopted by consumers for economic reasons, and, so far as he was aware, all staple articles of food were now freely available. The reply read somewhat as a disclaimer and misled us, along with others, into supposing that the Minister of Health was unable to offer the practical dietetic advice of which as a nation we stand so much in need just now, forgetting that—as appeared elsewhere in our columns—the issue of a pamphlet on these very matters had been foreshadowed by the Minister. It is, of course, well-nigh impossible for anyone to make general statements on food values which are not liable to be misconstrued. Professor Gowland Hopkins found this so early this year when his Huxley lecture, which we published in full, gave a section of the daily press occasion to bury "those d——d calories" along with all the carefully measured demands of the body which they represent and the slight intellectual effort required to appreciate them. After all, calories can be measured, while accessory food substances, until they have been isolated, cannot. We propose to spell "vitamin" in future without the "e" in order to avoid the appearance of spurious accuracy implied by the ending "ine," which should strictly now only be given to organic bases. When the researches being conducted jointly by the Ministry of Health and the Medical Research Council are completed, and the pamphlet follows, its issue will be very welcome.

ANÆSTHETICS FOR AN UNUSUAL PURPOSE.

THE National Anæsthesia Research Society, whose activities in America we have commented on with admiration on previous occasions, publish in their latest bulletin an interesting example of a novel use for anæsthetic administration. Hitherto what association there has been between anæsthetics and crime has been for the benefit of the criminal. Actually such an association is rare in real life, although very common in fiction. The novelists' criminal, we may remark *en passant*, when he employs chloroform has a positively supernatural skill in obtaining rapid results. The handkerchief appears to be applied to the victim's face one moment and the next he, or more often she, lies at the mercy of the administrator. The induction, moreover, appears to be as safe as it is rapid, for the victim always awakes. Anæsthetics have now been turned in real life against the criminal. They have been used to demonstrate the possibility of phonation on the part of a man accused of murder who steadfastly refused to utter a word for two weeks. The account presented[1] is not perfectly clear, but apparently the man was given nitrous oxide first, to what stage of narcosis we are not told, and then ether to the excitement stage. At this point he exclaimed loudly and the physician in attendance was satisfied that "he could have talked all along if he had so desired."

DELAYED REPORTS.

IN *almost identical words do the Sanitary Commissioner for the Madras Presidency and the medical officer of health for the county of Gloucester deplore the failure of subordinate health officers punctually to submit their sectional reports. The delay in each case has impeded the preparation of the larger and more comprehensive report from which alone hygienic lessons can be drawn, with the result that these lessons are unduly held back. Reports for 1919 are still coming in, and it is difficult to believe that they have not lost their freshness for the wider public whom every active-minded medical officer of health hopes to reach. We have more than once dwelt on the official report as popular educator, and we hope that this view may be found to lighten what is too often regarded as mere clerical drudgery. Everyone cannot hope to write with the racy pen of some county medical officers, but all should bear in mind the educational value of a prompt and vivid report.*

WE regret to announce the death of Dr. Henry Barnes, O.B.E., LL.D. McGill, consulting physician to the Carlisle Infirmary, and the author of well-known works on Cumberland medical topics.

AN Interim Report presented on April 12th by the King's Fund Policy Committee to King Edward's Hospital Fund for London recommends a careful inquiry to see whether the problem of voluntary hospital finance could be solved if the voluntary subscriptions of the charitable public were supplemented by a graduated system of patients' payments from those able to pay at the time of illness and by insurance on the part of those who are unable to do so, the hospitals agreeing to limit free treatment, except in emergencies, to those unable either to pay or to insure.

The Services.

QUEEN ALEXANDRA'S MILITARY FAMILIES' NURSING SERVICE.

THIS service, consisting of matrons, sisters-in-charge, and staff nurses, will take over the permanent nursing establishment of the military families' and military isolation hospitals. The rates of pay and pension will be the same as those laid down for the corresponding ranks in Queen Alexandra's Imperial Nursing Service.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lieut.-Cmdr. (D.) E. E. Fletcher to be Surgeon-Commander (D.).

Surg. Lieut. J. B. Crawford to rank of Surgeon Lieutenant-Commander.

ROYAL ARMY MEDICAL CORPS.

Temp. Lieut.-Col. E. W. White relinquishes his commission and retains the rank of *Lieutenant-Colonel*.

Major W. Byam relinquishes the temporary rank of Lieutenant-Colonel on reduction of establishment.

Temp. Major E. H. Marshall (Major, R.H. and R.F.A., T.F.) relinquishes his temporary commission.

Capt. and Bt. Major J. D. Kidd relinquishes the acting rank of Major.

Temporary Captains relinquishing their commissions and retaining the rank of Captain: E. J. Maxwell, J. A. Martin, R. H. Balfour-Barrow, P. G. Simpson, D. Evans, T. L. Davies, D. C. Smelzer, H. P. W. Lincoln, W. Pritchard-Airey, J. H. Whiteside, and A. G. Leitch.

ROYAL AIR FORCE.

Medical Branch.—A. F. Wright, A. E. Jenkins, and W. B. Wilson are granted temporary commissions as Flight Lieutenants. M. J. Cahalane, O. St. L. Campion, and S. E. Elphick are granted short service commissions as Flight Lieutenants.

The undermentioned relinquish their temporary commissions on return to naval duty: Wing Commander G. D. Bateman (Surgeon Commander, R.N.) and Squadron Leader A. R. Sharrod (Surgeon Lieutenant-Commander, R.N.).

EXCESSIVE PRESCRIBING BY PANEL DOCTORS.

(FROM A LEGAL CONTRIBUTOR.)

WHILE it may reasonably be supposed that every practitioner having charge of a panel is more or less acquainted with the rules under which he carries out his duties, he is probably not very familiar with the decisions of the tribunal which is called upon to consider alleged breaches of the rules. They are not reported, like ordinary cases, in the daily press, and are only published at long intervals. The following notes set forth some general principles laid down in the cases which have been reported; the references are to two volumes of reports published in 1917 and 1919 respectively as Parliamentary papers.

The Drug Fund.

With respect to excessive claims upon the Drug Fund, Article 40 of the National Health Insurance (Medical Benefit) Regulations (England), 1913, is in the following terms:—

> 40.—(1) Where it appears to the Panel Committee that by reason of the character or amount of the drugs or appliances ordered for insured persons by any practitioner or practitioners on the panel, the cost of the supply of those drugs and appliances is in excess of what may reasonably be necessary for the adequate treatment of those persons, the Panel Committee may, and if any representations to that effect are made to them by the Pharmaceutical Committee shall, make an investigation into the circumstances of the case, whether in respect of the drugs and appliances ordered by an individual practitioner or generally as to the orders given for drugs and appliances by practitioners on the panel.
>
> (2) The Panel Committee shall, after hearing the Pharmaceutical Committee and any practitioner concerned, make a report to the Committee, and if, after considering the report, the Committee are of opinion that an excessive demand upon the Drug Fund has arisen owing to orders given by a practitioner which are extravagant either in character or in quantity they may, if they think fit, make such deduction from the amount payable to that practitioner by the Committee as they think fit, and shall pay the amount so deducted to the credit of the Drug Fund: provided that the practitioner shall be entitled to appeal to the Commissioners, whose decision shall be final.

Appeals.

Appeals are dealt with by the Commissioners under the provisions of Article 51 of the Regulations, which empowers them either to decide the case without a hearing, or, if they think that a hearing is required, to authorise any two or more of their number to hear and determine the appeal. It is to be observed that the Panel Committee must make the investigation, and that they must listen to representations made by the Pharmaceutical Committee. All the cases which follow, except the last, were decided under Article 40; but it is important to notice that this Article was revoked and replaced by Article 9 of the Regulations made in 1916. Under this Article the Pharmaceutical Committee no longer takes any part in the proceedings; the Panel Committee may, if dissatisfied with the Insurance Committee's decision, refer the matter to the Commissioners, when both the Panel Committee and the practitioner concerned may be heard.

Notwithstanding this change, the following cases lay down some valuable principles. The Panel Committee may not delegate their powers. In one case the Panel Committee appointed five of their members as a subcommittee to investigate cases of alleged excessive prescribing, and the appellant was invited to attend, and attended a meeting of this subcommittee. He was not given an opportunity of appearing before the Panel Committee itself. It was held that the Panel Committee had no power under the Regulations to delegate to a subcommittee their duty of hearing the practitioner, and that the irregularity of procedure invalidated the Panel Committee's report.

It does not appear to be necessary that the Committee shall be satisfied by evidence on oath. They may ply their own knowledge and experience. In a case ided on March 16th, 1915, the Insurance Committee held money from the appellant on the ground that quantities of lin. methyl. sal. ordered by him were excessive. The appellant, in a written statement addressed to the Panel Committee, had put forward the plea that the circumstances of the neighbourhood where his patients resided were such as to call specially for lin. methyl. sal. The Panel Committee, after considering this statement, recommended that money should be withheld from the appellant, and stated in their report that in arriving at this decision they had acted "on their knowledge as general practitioners as to the quantity likely to be necessary." It was held that on this point the Insurance Committee were entitled to accept the expert opinion of the Panel Committee as conclusive.

Statistical and Other Evidence.

There must, however, be evidence of some kind. Statistical evidence does not generally suffice, standing alone, to justify the inference of extravagance; but in conjunction with evidence derived from the character of the prescriptions themselves and in the absence of satisfactory explanation by the doctor, it may assist both in establishing the fact of extravagance and in enabling a reasonable estimate to be made of the additional cost thereby caused to the Drug Fund. But where statistical evidence is put forward and the practitioner fails to give an adequate explanation of a charge of extravagance, it may be sufficient. So where the cost of the appellant's prescriptions calculated on this basis as compared with the general average of the panel doctors' prescriptions on a similar basis is represented by a percentage of 214·4. The actual cost of the prescriptions for the period of six months was £58 13*s.* 9*d.*, and the number of persons on his list was 262. Having these figures before them, together with the other evidence referred to above, the Panel Committee reported that they found that there was evidence of general extravagance and unnecessary frequency in prescribing, and that they estimated the excess thus caused at 50 per cent. of the total cost of the prescriptions. The Insurance Committee, on the recommendation of their Medical Benefit Subcommittee, accepted this estimate and decided to deduct £29 6*s.* 10*d.* from the doctor's remuneration. The Commissioners reduced the deduction to £15, but stated that in so doing "they have acted on the view that the provision for a reduction is largely intended to be a deterrent, and have had regard to the fact this is the first occasion on which a charge of extravagance has been made and established against this practitioner."

A Concrete Example.

The following is a good example of what has been regarded as extravagant prescribing.

The average cost of the appellant's prescriptions for two quarters per insured person on his list was respectively 12·67*d.* and 8·59*d.* as compared with a general average for all practitioners on the panel of the area of 6·21*d.* and 5·83*d.* In addition to this and other statistical evidence, there was a report which showed that orders for malt and oil had been given by the appellant much more frequently than was warranted by the dosage which he himself directed. The Commissioners found that the Insurance Committee were justified in arriving at the conclusion that there had been extravagance and dismissed the appeal from a deduction of £21 13*s.* 3*d.*

In a case in which several panel doctors were concerned (Vol. I., p. 92) the Panel Committee had taken the view that the investigation by them of particular prescriptions would be an undue interference with the doctor's treatment of his patient. The Commissioners, however, stated that this view was inconsistent with the proper discharge of the Committee's functions under the Regulations.

It is not sufficient for a Panel Committee to invite a practitioner, against whom extravagant prescribing is alleged, to inspect his own prescriptions and give explanation; individual prescriptions which appear to indicate extravagance should be put to the practitioner.

A claim on the part of a practitioner to discuss with the Panel Committee seriatim the whole of his prescriptions (amounting to some three thousand) and to have the insured person for whom the prescription was ordered in attendance at the meeting was held unreasonable and not warranted by the Regulations. (Vol. I., p. 103.)

It should be mentioned that in the Scotch case of Mitchell *v.* The Insurance Committee of the Burgh of Aberdeen, (1918) 1 S.L.T. 316, Lord Salvesen decided that the Committee were not bound to investigate every case treated by the doctor.

The Panel Committee must not, however, act upon mere guess-work. Thus a procedure under which the Panel Committee invite practitioners on the panel, the cost of whose prescriptions exceeds a certain average sum, to submit to the deduction of one-fourth of the excess, involves the substitution of a mechanical process for a proper investigation into individual cases, and is open to criticism on this ground. (Vol. I., p. 101.)

The practitioner, however, must be prepared to rebut a charge of extravagance. So where in the opinion of the Panel Committee as a body of medical practitioners the use of certain drugs appears *primâ facie* to exceed what is reasonably necessary for adequate treatment, it is not a sufficient answer for the practitioner concerned to say he honestly thought them necessary.

It has also been held that it is dangerous for a doctor to ignore the proceedings of the Panel Committee, for it has been held that a doctor who declines to attend the meeting of the Panel Committee at which his prescriptions are discussed does so at his own risk, and it does not lie with him to take an objection on appeal, if the Panel Committee's report in consequence appears less conclusive than would otherwise be the case.

A distinction is drawn between "active" drugs and those which are used for flavouring, &c. In one case (Vol. I., p. 112) the Commissioners laid it down that the question of the legitimate use of sweetening and flavouring agents is one of degree and proportion. The view adopted by the Panel Committee, that the latter drugs cannot be placed in the same category, therapeutically, as "active" drugs, and that a reasonable moderation should be observed in their use, was approved.

The panel doctor sometimes has occasion to call in a consultant. If the consultant orders expensive drugs it does not necessarily follow that the expense will be allowed. The Commissioners have decided (Vol. I., p. 116) that the fact that a particular preparation has been recommended by a consultant does not divest the panel doctor of his ordinary obligations, and he cannot justify the prescription merely by reference to the consultant's advice; but the recommendation is a circumstance of which account must be taken in deciding whether the preparation was reasonably necessary for the adequate treatment of the patient.

As to proprietary medicines, it has been held that the use of such articles costing more than the B.P. preparations, though justifiable in exceptional cases, cannot be supported merely on the ground that the patients preferred the article. The view that the patient's judgment is to be the criterion of the necessity for the use of particular medicines would involve a dangerous abdication by medical practitioners of their professional responsibilities.

The question of the latitude to be allowed to a doctor's individual preference in methods of prescribing was considered in relation to an alleged excessive use of liquor morphinæ. The Commissioners decided, in the absence of evidence that the insured persons on the appellants' lists differed from those on the lists of other doctors, that the use of a drug such as liquor morphinæ in 75 per cent. of the scripts issued by one of the appellants could only be held reasonably necessary on the assumption that all persons who are not being treated on such methods are deprived of adequate treatment.

In another case a doctor, according to the report of the Commissioners, had "made extensive use in his practice of two proprietary articles—namely, ferro-glidine, stated to be a preparation of iron especially devised to secure easy assimilation; and iodex, a preparation of iodine in the form of an ointment, said to possess the advantages of being rapidly absorbed and of not staining. On careful consideration of the full evidence given as to the relative advantages of these preparations and of other preparations of iron and of iodine respectively, which might have been used for the same objects, we are not satisfied that many, at all events, of the patients treated by the use of these remedies could not have been treated with equal benefit, and at much less cost, in other ways." The Commissioners, however, made it plain that what they objected to was the routine use of these articles.

The individual discretion of the doctor must not be unduly interfered with. Thus, in deciding whether particular drugs are "reasonably necessary," due allowance must be made for the personal element, and within reasonable limits a doctor should be allowed to follow methods of treatment most congenial to him. But the exercise of individual judgment does not necessarily lead to the use in all cases of more expensive forms of treatment, and if a proneness to use more expensive drugs is coupled with a very high average cost, strong evidence would be required to show that the high cost is due solely to the conscientious exercise of a discriminating judgment.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

MADRAS CONSULTATIVE HEALTH COUNCIL.

THE Consultative Council of Public Health, the members of which were announced a few weeks ago, met for the first time on Feb. 12th at Fort St. George. At a previous meeting of the Board of Health suggestions had been made to divide up the Consultative Council into six committees, each committee to be responsible for a specified group of subjects. It was felt that in this way the Consultative Committee would be able to deal more efficiently and more speedily with the many problems which it would have brought to its notice. At its first meeting the Consultative Committee agreed to the formation of the following committees: (1) the Committee for Education and Research; (2) the Committee for Administration; (3) the Committee for Preventive Medicine; (4) the Committee for Water-supply, Drainage, &c.; (5) the Coördination Committee; (6) the Housing Committee.

Scope of the Sectional Committees.

The first Committee, consisting primarily of professional men, but including also a district board president, a sanitary officer, and an educational officer, would deal with such subjects as medical schools and colleges and their extension, location, curricula, &c., and the training of all classes of sanitary officers from medical officers of health downwards. The possibility of a Provincial Research Institute would also come into its purview, along with determination of standards.

The Committee for Administration would deal with matters connected with medical institutions, such as the standardisation of equipment, buildings, the provision of emergency wards in dispensaries, the important matter of itinerating dispensaries, and hospital accommodation for infectious diseases, whilst it would also deal with conditions of service of sanitary officers and the expansion of nursing and midwives' service. The members of this committee, with the exception of the Surgeon-General, are presidents of district boards and chairmen of municipal councils, but at least one sanitarian may also be considered essential.

The Preventive Medicine Committee, of which the Surgeon-General is chairman, deals with epidemic diseases like cholera, small-pox, plague, malaria, and the investigation of the history and periodicity of epidemics in South India is perhaps one of the most urgent questions which will arise.

The fourth Committee deals with the all-important problems associated with water-supply and drainage, and if it can hasten by a day some of the large schemes which have been held up for so long in the Madras Presidency it will have justified its creation.

The Coördination Committee has a difficult part to play. It will endeavour to coördinate the work of local bodies *inter se*, and to enlist voluntary agencies, delegating specific services to them and demarcating spheres of work, whilst encouraging the formation of district committees of public health. It will also have much to do with maternity work, as well as inspection of school children. But its most important duties will be in organising voluntary aid.

The Housing Committee will deal with civic surveys, town-planning schemes, coöperative buildings, &c., and its personnel comprises engineers, sanitarians, municipal chairmen and voluntary workers, along with the new director of town planning, and the chairman of the Madras City and Suburban Trust. Some of these committees have already met, and as most of the members are also members of the Legislative Council, when these several questions arise in the House they will be able to guide the Council.

An Ambitious Programme.

To indicate the work undertaken by these committees mention may be made of some of the resolutions passed by the Committee for Coördination at its first meeting. These include the following:—

(1) Recommended that the committee interview the Council of the Health and Welfare Association regarding the coördination of various associations, and (2) recommended that voluntary associations should be asked what they can do in the way of undertaking the following services: (*a*) maternity and infant welfare, (*b*) propaganda work, (*c*) ambulance and first-aid, (*d*) utilisation of students, boy scouts, and girl guides in public health, (3) recommended that the functions of the District Committee of Public Health should comprise provisionally the following:

(*a*) organisation of a district health service, (*b*) duplication of medical staff in order to bring medical relief within reach of rural populations, (*c*) to establish a record of the history and periodicity of epidemic disease within its jurisdiction.

No one will deny that this is an ambitious programme in itself, but it is only a fraction of what requires to be done, and it is to be hoped that some real benefit will accrue to public health in South India from the work of the Consultative Council.

Report of Sanitary Commissioner.

The Sanitary Commissioner's Report for 1919 has recently been published. As the Government remarks, "the utility of the report is greatly impaired by its late receipt, and the failure of certain local authorities to submit their returns punctually is unsatisfactory." The report covers a wide range of subjects.

In every district the birth-rate is markedly below the average for the five years ending 1918, and although defective registration is the cause assigned, the Government does not altogether accept this view and considers that the Sanitary Commissioner should endeavour by intensive examination in selected areas in each district to arrive at some coefficient of error to decide to what extent, if at all, the statistical decline in birth is real. A curious commentary made by the Board of Revenue is quoted—viz., that the registration of vital statistics is less satisfactory in areas where it is compulsory than in areas to which compulsion has not been extended. Public health in 1919 was under all heads much better than in 1918, and the death-rate in many districts was below the average for the previous five years. At the same time a very considerable number of districts and municipalities showed a very high death-rate, and there seems little doubt that influenza continued during 1919 to take its toll of victims over large areas in the Presidency.

Infantile mortality throughout the Presidency is appallingly high, and, as Government remarks, "does not reflect credit on local self-government." In Madras City, in spite of the child-welfare scheme which is now three years old, the rate is 332 per thousand, whilst the Presidency average is 246·2. Cholera accounted for 93,262 deaths, but so long as the provision of protected water-supplies is so backward—45 out of 74 municipalities having no protected supply—it is very unlikely that cholera will be effectively controlled. Moreover, nothing is known of the history and periodicity of the disease even in those areas most susceptible to infection, and this aspect of preventive work must receive attention before any definite policy can be laid down in regard to the protection of water-supplies.

Plague deaths totalled 5645, against 12,859 in 1918, but it is suggested that a more comprehensive programme of preventive measures should be drawn up, including intensive rat destruction, the provision of rat-proof godowns, &c.

General sanitation and conservancy are defective, and few municipalities are provided with a sufficiency of public or private latrines. Of 16 posts sanctioned for health officers only four are filled, as medical men are very reluctant to accept service under municipal councils. Even men qualified as sanitary inspectors avoid service under local bodies if they can get other employment, and this is not surprising when one is acquainted with the complete lack of interest taken in public health even by the more advanced local bodies.

Madras, March 17th.

HUNGARY.

(FROM OUR OWN CORRESPONDENT.)

The University of Kolozsvár (Klausenburg) in Budapest.

As Kolozsvár, the capital of Transylvania, has been in Roumanian territory since the Treaty of Versailles, the University of Kolozsvár (the Francis Joseph University, so named because it was erected at the private expense of the late King of Hungary), has been taken over by the Roumanians in the second half of the 1919-20 school year. The name of the University and the language in which lectures are delivered have been changed. Several professors have been asked to take the "oath of faith," which would have enabled them to retain their positions on understanding that they learnt Roumanian, after ich they would be required to lecture in that guage. Most of the lecturers have, however, refused take this oath, preferring to run the risk of dis ssal. Numerous professors and lecturers have voluntarily left Kolozsvár (Roumania) and have repatriated themselves by coming to Budapest. At the latter city it was a very difficult matter to house the university suitably in view of the great scarcity of available accommodation. The offices of the rector and dean have been placed in the building of a "middle school," but various university institutions are now scattered over the whole city. The great distances to be traversed between them cause serious difficulty in the working of the university, which at present contains 600 students. It is intended to move the university to Szeged or Debretzin. The former city (population about 150,000) has offered two palaces for the buildings, and has guaranteed suitable accommodation for all members of the staff, in addition to promising contributions towards maintenance, amounting to several million kronen. A decision will be reached by the university authorities in September.

A Professor's Relations with Bolsheviks.

In the autumn of last year the Hungarian Government issued an order that investigations should be made into the behaviour of public officials during the period of Bolshevik rule in Hungary. University professors and lecturers have also been considered as public officials, and those found to have shown Bolshevik tendencies were discharged from their positions. After these investigations had been held there appeared in a Budapest daily paper an article headed "Dr. Emil Gross, the Bolshevik University Professor." In this article the professor (who is well known in England, having been president of the Hungarian Section of the International Medical Congress in London in 1913) was seriously slandered. He was said to have erected marble tablets in his clinic to commemorate the visits of princesses who consulted him during the war, but to have taken them down during the Bolshevik revolution. The article also contained the indictment that Professor Gross offered his professional services to Bela Kun, the Bolshevik dictator, as his family doctor. Professor Gross, as a university man, was empowered by the Minister for Public Instruction to take legal proceedings against the writer of the article. The case was heard and the journalist who was responsible for its publication said that it was the work of a medical student, who confessed to having written it, but stated that he had given it to the journalist to edit and confirm the contents before publication. The article had appeared as it was written, however, and the journalist was sentenced to 60 days' imprisonment for calumny and fined the sum of 1200 crowns.

An Interesting Case of Medical Secrecy.

One day during March a venereal diseases specialist, seated in the large warm-water basin in the antechamber to the steam hall of the Turkish baths at Debretzin, recognised in a young man who was about to enter the water one of his own patients who had consulted him two weeks previously for an extensive syphilitic sore on the penis. The physician had ordered him calomel ointment, and, knowing that the sore could not be healed, got out of the water, went up to his patient, and whispered to him that he must not enter the basin on account of his chancre. The man told him that the chancre was already healed, whereupon the doctor remarked that he declined to sit with him in the same basin, and that he would summon the manager of the baths if the other persisted in entering the water against his advice. As the patient refused to comply with the request the specialist sent for the manager and explained matters to him. The latter pointed out that the rules of the public baths prohibited men with wounds, skin diseases, &c., from entering common baths. The young man thereupon dressed himself, went away, and consulted another specialist, who gave him a written certificate that on that day his sore had healed, leaving only a hard infiltration. The young man sued the doctor for trespassing the medical secrecy laws, but lost his case, the court decreeing that the specialist only carried out his professional duty, being right to presume that the chancre had not healed in so short a time, and acting in the interests of the community in so doing.

Persecution of Jewish Students at Budapest University.

A few days ago some women students, believed to be Jewesses, being seated in the front at a lecture by Dr. Paul Háry, professor of physiological and pathological chemistry, were ordered by certain male students to move to the back benches. The incident was reported in a morning paper, and on the following day, after a lecture, a student rose and declared that until the newspaper article had been withdrawn or corrected Jewish students would not be admitted to the lectures. No correction, naturally, did appear, for the article had contained only the truth. The door of the Institute of Physiological and Pathological Chemistry was barricaded against Jews, who were told they would only gain admission by revealing the name of the writer of the article. Professor Háry finally came and persuaded the men concerned, who belonged to the Anti-Semitic Union of University Students, to desist from such measures against their comrades, and undertook to find out who made the matter known to the press, promising to express his reprobation of this publication of the internal affairs of the University.

Foreign Bodies in the Stomach.

In Szombathely a commercial clerk, 19 years of age, recently sought the advice of a club doctor for pains in the stomach; on palpation the latter diagnosed a tumour and sent him to hospital, where X ray examination revealed the presence of material, probably metal, which gave a large shadow. Dr. Peto extracted at the operation 43 wire nails, 3½ inches in length, together with 20 pieces of lead of the same length as the nails. Finally he found among the intestines the blade of a penknife. The aggregate weight of these objects amounted to more than 500 grammes. After being awakened from narcosis the man was asked how the foreign bodies came to be in his stomach, but said he did not know how he could have swallowed them. His relatives stated that he was mentally unbalanced and excessively religious; they thought it probable that he swallowed the objects during his periods of exaltation.

URBAN VITAL STATISTICS.

(Week ended April 9th, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18½ million persons, the annual rate of mortality, which had been 13·9, 13·0, and 13·0 in the three preceding weeks, fell to 12·5 per 1000. In London, with a population of 4½ million persons, the death-rate was 13·4, or 0·2 per 1000 above that recorded in the previous week, while among the remaining towns the rates ranged from 4·1 in Acton, 6·3 in Ilford, and 6·4 in Edmonton, to 17·1 in South Shields, 17·2 in Halifax, and 17·5 in Oldham. The principal epidemic diseases caused 228 deaths, which corresponded to an annual rate of 0·6 per 1000, and comprised 64 from infantile diarrhœa, 57 from diphtheria, 52 from whooping-cough, 38 from measles, 14 from scarlet fever, and 3 from enteric fever. Whooping-cough caused a death-rate of 1·5 in Burnley, and diphtheria of 2·5 in Exeter. The deaths from influenza, which had been 151, 122, and 130 in the three preceding weeks, fell to 97, and included 38 in London and 5 in West Ham. There were 3453 cases of scarlet fever and 2626 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 3535 and 2689 respectively at the end of the previous week. During the week ended April 2nd 5 cases of encephalitis lethargica were notified in the County of London, and comprised 2 in Wandsworth, and 1 each in Camberwell, Paddington, and St. Pancras. The causes of 32 of the 4454 deaths in the 96 towns were uncertified, of which 7 were registered in Birmingham, 6 in London, and 3 in South Shields.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 17·8, 15·3, and 15·5 in the three preceding weeks, fell to 15·1 per 1000. The 343 deaths in Glasgow corresponded to an annual rate of 16·3 per 1000, and included 27 from whooping-cough, 3 from infantile diarrhœa, and 2 from scarlet fever. The 122 deaths in Edinburgh were equal to a rate of 14·3 per 1000, and included 3 from infantile diarrhœa, 2 from measles, and 1 each from whooping-cough and diphtheria.

Irish Towns.—The 154 deaths in Dublin corresponded to an annual rate of 19·0, or 0·2 per 1000 below that recorded in the previous week, and included 4 from infantile diarrhœa, and 1 each from enteric fever and scarlet fever. The 130 deaths in Belfast were equal to a rate of 16·1 per 1000, and included 9 from whooping-cough, 3 from measles, and 1 each from enteric fever and infantile diarrhœa.

Public Health.

ANNUAL REPORTS OF MEDICAL OFFICERS OF HEALTH.

COUNTY OF DERBY.

Dr. Sidney Barwise makes some interesting remarks on the subject of the prevention and treatment of tuberculosis in his annual report for 1919. In common with most parts of England, there has been in Derbyshire during the previous few years an increase in the number of cases of tuberculosis and deaths resulting from the disease. The number of notifications and deaths respectively from all forms of the malady were in 1915, 990 and 557; in 1916, 1098 and 552; in 1917, 1146 and 621; in 1918, 1123 and 667; and in 1919, 1176 and 525. During the last 30 years, however, the death-rate from pulmonary tuberculosis in the county has declined much more rapidly than in England and Wales as a whole.

If any real advance is to be made in the prevention and treatment of tuberculosis, those engaged in the work should have in mind the many unsolved problems connected with the disease and take every opportunity of increasing our knowledge of the subject by observation and inquiry concerning aspects of the question that still remain obscure. As a result of study of the literature, Dr. Barwise gives an excellent synopsis of the more modern views, and allusion may be made to certain of the points discussed by him. Tuberculosis is the most widespread of diseases; it accounts for 10 per cent. of all deaths in England and Wales. It is widely distributed throughout the world. In America it is more common amongst the negroes, although it was almost unknown amongst them while they were in slavery. After the blacks, the Irish suffer most in America, while the incidence of the disease among the Jews is relatively small. Among the North American Indians tuberculosis was unknown while they were uncivilised. In 1896 half of certain tribes had been exterminated, in spite of a birth-rate of 41 per 1000. In nine reservations 66 per cent. of the deaths were from tuberculosis.

A few years ago the generally accepted view was that phthisis was due to inhalation of tubercle bacilli in dust from dried sputum, and that over 50 per cent. of glandular and abdominal tuberculosis was due to the consumption of milk containing the bovine type of the tubercle bacillus. Investigations on the portals of entry into the body of the specific micro-organism have modified our views on this subject. It is probable that the risk of infection from dried sputum is not very great. A leading authority, F. M. Pottenger, has recently described tuberculosis as primarily a disease of the lymphatic system, and there is a considerable amount of evidence in favour of the view that the tubercle bacillus gains access to the body through the tonsils or intestine. The droplets sent out in coughing by a person in certain stages of the disease are probably one of the chief sources of infection. Walsham, in 1903, called attention to the tonsil and the cervical glands as a common channel of entry. He found that in 34 consecutive *post-mortem* examinations on the bodies of patients who had suffered from tuberculosis, the tonsils were infected in no less than 20. Beattie and Dixon express the view that the commonest mode of entry in the human subject—*except in the case of young children*—is by way of the tonsils, and perhaps in some cases by way of the teeth. The bacilli pass to the cervical glands, and into the lungs by way of the peri-bronchial lymphatics. From the root of the lung the path of infection may be outwards and upwards, involving the apex of the upper lobe, or it may spread fanwise and involve the pleura. There is now fairly general agr
with Sanarelli's view that man only survives by
acquired immunity as a result of a mild att
tuberculosis early in life. Support is, of
to this view by the large proportion of bodies
either active or healed manifestations of the

post-mortem examinations made upon persons who have died from other causes.

Having discussed many of the problems in connexion with the transference of the malady Dr. Barwise makes a few practical suggestions on the public health application of the lessons learned. The improvements necessary in housing are better ventilation, better facilities for washing, better places for storage of food. The efforts of health visitors should be concentrated on preventing infection during the first few years of life. The child should not be allowed to crawl on the kitchen hearthrug, but have a clean washable crawling rug, and its hands and face must be washed before each meal. If infected during the first year of life the result is almost always fatal, and children should be removed from tuberculous mothers, as Bang, of Copenhagen removed the calves from tuberculous cows. Again, the campaign against tuberculosis in cattle must be proceeded with, and until milk is available from certified tubercle-free cows, that given to infants under two years of age must be sterilised. We must remember, however, that the child has to acquire immunity. It cannot always be kept wrapped up in cotton-wool. After it has reached the age of 2 years, it should, in Dr. Barwise's opinion, take its risk in acquiring immunity through a localised tuberculosis by allowing it occasional small doses of the ordinary milk of commerce.

COUNTY OF GLOUCESTER.

In presenting his annual report for the year 1919, Dr. J. Middleton Martin again refers to the difficulty experienced in obtaining from the district medical officers of health copies of their annual reports within a reasonable period of the end of the year under review. Many of these were sent to the county council at a very late date, thus impeding the preparation of the annual report for the county as a whole.

The number of births registered in Gloucestershire during 1919 was 5275, giving a rate of 16·4. This is the largest figure since 1916, and there is a distinct tendency toward a return to pre-war rates, though the recovery is as yet by no means complete. On analysis of the figures it is found that, when comparison is made with 1917, which was the year of lowest birth-rate, there has been an increase of only 9 per cent. in legitimate births and of 30 per cent. in illegitimate births. In rural districts the increase in legitimate births is as low as 5 per cent., and the corresponding figure for illegitimate births is 53 per cent. The total death-rates in both urban and rural districts are the lowest recorded since 1914. The rate for the whole county was 14·0, as compared with 13·8 for England and Wales. The statistics for 1919 show that influenza was again responsible for an unusually large number of deaths (335), though for by no means so many as in 1918 (849). Bronchitis was the cause of death in 319 cases, as compared with 234 in 1918, 292 in 1917, and 293 in 1916. The number of deaths ascribed to heart disease was 670, which is the maximum recorded, though not greatly above the numbers for 1917 and 1916, which were 652 and 650 respectively. The number of deaths from pneumonia was 222. From pulmonary tuberculosis it was 235, as compared with 329 in 1918 and 361 in 1917.

RHONDDA URBAN DISTRICT.

Dr. J. D. Jenkins's annual report for the year 1919, though not yet restored to its pre-war dimensions, contains much interesting material relating to the health and sanitary circumstances of the district. The general death-rate for the year under review was 13·1 as compared with a rate of 15·9 in 1918, and an average rate of 14·4 for the previous 10 years. The zymotic death-rate of 0·7 is the lowest for the last 30 years, and is less than half that of the previous year. The infantile mortality-rate was 111, which is rather higher than that for the two previous years. Housing is one [illegible] the chief public health problems in this district. [illegible] tendency to overcrowding which existed before [illegible] war has since become much emphasised. It is [illegible]lable that 1200 tenements give lodgement to more [illegible] two persons per room. As a result of inspection of over a fourth of the houses in the district within recent years it may be stated that between four and five thousand houses intended for the accommodation of single families have become occupied by two or more families per house. Overcrowding is steadily increasing owing to the dearth of houses, and it is estimated that it will be necessary to erect approximately 1000 houses a year to remedy the existing unsatisfactory state of matters in this respect. The majority of existing houses are comparatively new, commodious, and generally fairly well built of native Pennant sandstone, but the number provided with baths forms a small minority. The defects found in the houses that have recently been inspected were, for the most part, in the nature of general dilapidation attributable to inattention or neglect during the war years and consisting of defective walls, roofs, doors, and windows, insufficient or broken yard-paving, and dilapidated sanitary conveniences. Even before the war difficulty was experienced by owners of property in obtaining skilled labour, and this, of course, became progressively greater and ultimately insurmountable during the war years. The position was further aggravated by the increase in the price of building material and by the restrictions imposed upon its purchase. Having regard to these difficulties the Rhondda urban district council, under the provisions of the Housing Acts, 1890 to 1919, have decided to undertake themselves to a greater extent than formerly, the repairs of houses not in all respects reasonably fit for human habitation in instances where the owners fail to comply with the requirements of notices served upon them. Information concerning 115 such houses has been lodged with the surveyor to the council, whose department is entrusted with the work, which is now proceeding in three portions of the district simultaneously.

COUNTY BOROUGH OF BIRKENHEAD.

In the preface to the annual report for 1919 Dr. D. Morley Mathieson, who was appointed as medical officer of health of this county borough on the death of his predecessor, Dr. Sidney Marsden, makes reference to the circular issued by the Ministry of Health in January, 1920, in which it is stated that a survey in annual health reports of existing conditions and arrangements is specially needed at the present moment—

> "to form the basis of that careful and comprehensive scheme of health developments generally which it is hoped may shortly follow, in every locality, upon the recent unification in the Ministry of Health of the various central functions in respect of all matters affecting the health of the people; since this unification of the central administration implies and, indeed, cannot be effective without a corresponding coördination of local health activities."

Dr. Mathieson thinks that the Ministry's pronouncement will be welcomed as indicating a new policy and that it will have the effect of encouraging each local authority to look upon its health problem as a whole. This means getting away from the sectional view that the health of an infant, the health of a child attending school, the health of a tuberculous workman, the health of an expectant unmarried mother, are quite distinct problems calling for separate staff, isolated premises, and different methods. It means realising that all these and many other sides of public health work are essentially one, and that only when the machinery for dealing with them is gathered into one central workshop, and, so to speak, driven off the same shaft, can fully coördinated results be obtained.

Birkenhead occupies an area of 3850 acres, or about six square miles, and is the largest borough in Cheshire. In 1881 the population of the borough was 84,006; in 1891, 99,857; in 1901, 110,915; in 1911, 130,794, and the Registrar-General estimates the population in 1919 for the death-rate at 148,052, and for the birth-rate at 154,226. During the year 3385 births were registered, giving a birth-rate of 21·9 per 1000. There were 2067 deaths and the death-rate was 13·9. The infantile mortality-rate was 102 per 1000 births.

MISS RUTH DARWIN has been appointed a Commissioner (unpaid) of the Board of Control.

Correspondence.

"Audi alteram partem."

PREVENTION OF HEART DISEASE.

To the Editor of THE LANCET.

SIR,—The leading article under this title in your issue of April 9th regrets that while much work is being done on the clinical side of heart disease, the preventive aspect is comparatively neglected, and you commend to us the "thoroughgoing campaign" directed towards prevention and inaugurated in America. Doubtless your advocacy will command general sympathy, but at the best any practical outcome from it will be delayed. In the meantime we must utilise the measures which are at hand. Hence I repeat once more the proposal that the recognition of rheumatic events in any member of a family ought to be an occasion for warning parents of the risks run by their children even from apparently slight illnesses. The mischief in a large proportion of cases of cardiac disease is effected during the non-arthritic forms of rheumatism—tonsillitis, chorea, febricula, &c. Parents do not know this truth, and only when they know it will they realise the importance of giving their children early and complete rest in the disturbances just named. Were this early and complete rest generally practised there is at least a chance that many children would be saved from the terrible misfortune of organic heart disease. The responsibility rests with the medical profession, and it can be discharged by the universal adoption of the course here proposed. For the "national campaign" we needs must wait. But the individual practitioner has his opportunity here and now, and though it does not pretend to heroic possibilities it lies in the line of duty and is not without the promise of reward.—I am, Sir, yours faithfully,

Harley-street, W., April 12th, 1921. C. O. HAWTHORNE.

TREATMENT OF PSEUDO-DIPSOMANIA.

To the Editor of THE LANCET.

SIR,—Although probably every practitioner meets with cases of alcoholism in his practice, it does not appear to be universally recognised that in practically all such cases the only possible course is complete and total abstinence. I have come across so many of these unfortunate patients who have been advised to take one or two glasses a day and no more, with invariable failure, that I venture to write in the hope of saving some of the others from a like fate.

It cannot be too generally known that no case of pseudo-dipsomania (drinking in bouts) can, as a rule, take a single glass without craving following, and that whilst the individual who is liable to chronic alcoholism can for a short time take alcohol in moderation, it is utterly impossible for him to do so for any length of time. It is true that some pseudo-dipsomaniacs require a comparatively large amount of alcohol to start an attack, and that some of these habitually take beer with their meals without an attack, though in every such case which I have seen their period of immunity has been ended by their taking whisky. But in both these two forms total abstinence is the only possible line to take to avoid relapse. It is more difficult to speak with confidence regarding the true dipsomaniacs, who get attacks of craving at regular or irregular intervals, whether they take alcohol or not. Some of them can drink in moderation between their attacks. Some can be radically cured—the only form of alcoholism which can, though few have so far recovered.

In certain cases the attacks always end with a heavy discharge of urates, and I have found that in a few of these a bottle of Contrexéville taken every day for three days running every fortnight, and a saline purgative once a week will keep off attacks for long periods. Six such patients treated in this way have remained well for over six years, one of them who suffered for over 20 years having had no relapse for eight and a half years. In others repressions of various kinds seem to be the acting cause, and cure follows when they are unearthed, either by hypnosis or psycho-analysis. Many of them unfortunately suffer from pseudo as well as true dipsomania, and, of course, in such cases total abstinence is a sine qua non.

Nothing is more pathetic than the struggle against hopeless odds which these unfortunate patients undergo when trying to follow the well meant but fatal advice to take only a limited amount. It is impossible. Their only choice lies between total abstinence and drinking in excess. I am, Sir, yours faithfully,

Welbeck-street, W., April 6th, 1921. HUGH WINGFIELD.

BROMISM THROUGH MATERNAL MILK.

To the Editor of THE LANCET.

SIR,—With reference to an annotation appearing in THE LANCET of April 9th, under the above title, the notes of the following case, which occurred in my practice, may be of interest.

A breast-fed infant of 5 weeks was seen by me on April 11th, 1912, on account of a rash on the face and scalp which began as a single spot on the left cheek on April 4th, and by April 8th had spread over the face and scalp. On April 11th there was a papulo-pustular eruption on the face and scalp, each spot being round, raised on an inflamed base, and covered with a fairly thick dark crust. Most of the places were the size of a threepenny-bit, but three on the scalp were the size of a sixpence. The rash seemed to give the patient pain. Otherwise the child seemed to be perfectly well. The temperature was, and continued to be, normal. On April 13th there was a spot exactly similar to the above on the left wrist. The eruption seemed to me to be a typical bromide rash and difficult to account for, the child being breast-fed. Inquiry, however, elicited the fact that the mother had been taking a mixture of pot. brom. ʒ iss aq. ℥vi. in one table-spoonful doses thrice daily for ten days before the first appearance of the rash and until April 11th. The mother was duly instructed to avoid taking the drug. On the 24th there was a fresh crop of spots similar to the previous, and due apparently to the fact that the mother had, contrary to instructions, been taking the bromide mixture again since the 17th. The diagnosis was confirmed on the 20th by the opinion of a well-known dermatologist who saw the patient, but no examination of the mother's milk for the discovery of bromine was made. Recovery was not complete until the middle of June. A noteworthy feature of the case was the fact that the dose of bromide was only gr. viiss. taken thrice daily for ten days before the first appearance of the rash.

The character of the eruption was exactly that which is not infrequently seen in infants who are taking bromide as medicine by the mouth, but previous to this case it had not fallen to my lot to see a case where bromism had been produced apparently by administering bromide to the nursing mother.

I am, Sir, yours faithfully,

Streatham, S.W., April 9th, 1921. HARRY E. SMITH.

THE DIPHTHERIA SWAB ON DISCHARGE.

To the Editor of THE LANCET.

SIR,—There seems to be some confusion between the financial and clinical value of the diphtheria swab on discharge. If the cost is not considered, I do not think anybody would maintain that we should not obtain information from any method that may be available, and in this connexion it is well to remember that a positive result has a clinical as well as an administrative value, in enabling treatment to be directed to the infected area. When in charge of the Manchester City Fever Hospital I found that many diphtheria convalescents had positive noses and negative throats, and that the attention thus directed to the nose enabled one to adopt useful measures for ridding the patient of the bacilli. Surgical treatment, both in the throat and nose, was often necessary and successful.

Financially, the cost of the examination of 200 swabs in a central laboratory costs less than the hospital treatment of one return case. I do not think anyone will deny that—as pointed out by "M.O.H." in your last issue—the swabbing of convalescents does sometimes diminish the incidence of return cases, and in my own experience this influence was both beneficial and well marked. The bacteriology can be done more *cheaply* by an assistant medical officer of health because he is not paid much—if at all—for the work, but the advocates of this procedure do not always seem to realise that something more than a microscope and appropriate stains are necessary. It is in the preparation and accurate standardisation of media that the central laboratory has the advantage.

I am, Sir, yours faithfully,
A. KNYVETT GORDON, M.B.
Bedford-square, W.C., April 9th, 1921.

THE FIGURES OF VENEREAL DISEASE.

To the Editor of THE LANCET.

SIR,—My fault. I am sorry. The increase of 23,000 V.D. cases was "*at the London hospitals,*" not "*at the London Hospital.*" I misread my brief.

I am, Sir, yours faithfully,
April 9th, 1921. KNUTSFORD.

VENEREAL INFECTION IN RHINE ARMY.

To the Editor of THE LANCET.

SIR,—In a letter of mine you recently published (March 26th) I showed how very much better the American Forces in Germany were *in their control of* venereal infection than were the British Forces. The American rate I quoted was for the period January–October, 1920—viz., 142 per 1000 per annum. This rate has now been considerably reduced, and for the period Nov. 1st, 1920, to April 1st, 1921, the American rate is 114 per 1000 per annum. The lowest rate officially stated for the British Forces is 168 per 1000 per annum for the period Jan. 1st, 1920, to Jan. 31st, 1921, and the highest rate, quoted semi-officially, is that given by Dr. E. B. Turner in November last—viz., 500 per 1000 per annum.—I am, Sir, yours faithfully,

ETTIE A. ROUT,
Late Hon. Secretary, New Zealand Volunteer Sisters.
April 11th, 1921.

THE VALUE OF THE QUASI-CONTINUOUS TEMPERATURE RECORD.

To the Editor of THE LANCET.

SIR,—Since our paper on the Value of the Quasi-Continuous Temperature Record in the Early Diagnosis and Prognosis of Tuberculosis appeared in THE LANCET of March 19th we have received a number of inquiries as to how we take these temperatures—one as to whether it is not very disturbing to the patient to have his temperature taken at such short intervals. May we point out *that the method of taking* these temperatures was described in THE LANCET of Feb. 5th and 12th, 1916, and that the records published in our last paper are simply in continuation of work begun some eight years ago? The thermometer used—a rectal thermometer—is left in position for 24 hours or more (the patient lying in bed), except when the patient has to use the night-stool. One of us lay in bed with the thermometer in position for the greater part of six weeks. All aver that they experience no inconvenience even when the thermometer is left *in situ* for several days. The process of recording the temperature is purely mechanical and automatic.

We are, Sir, yours faithfully,
G. SIMS WOODHEAD.
P. C. VARRIER-JONES.
Cambridge, April 11th, 1921.

A CONTROLLED STUDY OF SANATORIUM RESULTS.

To the Editor of THE LANCET.

SIR,—If all investigations and trial of new methods of treatment were carried out with such patience and control as Dr. E. Ward has shown in his article in your issue of March 12th, it would be better for all concerned—viz., the patients, the doctors, and the State. Dr. Ward, who may be supposed to have begun his work with a prejudice in favour of sanatorium methods, has published his conclusions with a candour that is convincing. My own experience distinctly supports his experience. It is to be hoped that his article will be read by the lay enthusiasts who have been misled by the lay press, and especially by members of county councils and insurance committees, who can hardly listen to a suggestion that sanatoriums have failed to do a tithe of what was promised. I cannot help thinking that if much of the money which has been spent on sanatoriums had been used to enforce by-laws regarding fresh air and sunlight in cottages we should have had better results.

I am, Sir, yours faithfully,
Plymstock, April 6th, 1921. S. NOY SCOTT.

A FATAL CASE OF CŒLIAC INFANTILISM.

To the Editor of THE LANCET.

SIR,—Dr. R. Miller, in presenting in your issue of April 9th *the view of* cœliac disease that he supports, might, I think, have referred to the fatal case published by Dr. Hugh Paterson and myself in THE LANCET, 1914, i., p. 1533, *under the title,* "*The Occurrence of* Ascites of a Non-tuberculous Origin in Chronic Recurrent Diarrhœa in Childhood." I believe it to be in this country the first complete proof by necropsy of a clinical sign which is well recognised in the cœliac affection, though perhaps hardly yet generally appreciated. Ascites is so intimately associated in our minds with abdominal tuberculosis in childhood that its occurrence in a wasting disease with diarrhœa tempts us strongly to decide that the condition must be tuberculous. *The* completion of the proof of its non-tuberculous nature is thus, I think, worth a reference in a paper dealing with the necropsies upon cases of cœliac disease. It is *of some interest that a* wide-spread leucocytic infiltration of the intestinal walls and pancreas was found in this case as in the one criticised by Dr. Miller in his paper. There is no doubt that Dr. Miller has made a valuable contribution to the subject by publishing his case, which was investigated by a skilled pathologist; whether his conclusion that the disease is "a digestive fault" independent of organic affection is correct the future must decide, though in my opinion he does not gain by ruling out cases described by others which he had no opportunity of seeing himself. My experience of cœliac disease has been that it may appear suddenly in classical type or follow upon a definite entero-colitis; *it may* be complicated by a subsequent entero-colitis or by serious constipation with great atony of the bowel. Is it "independent" of organic change? Possibly; but I still think we require more research upon the subject, and prefer to suspend my judgment.

I am, Sir, yours faithfully,
F. JOHN POYNTON, M.D.
Devonshire-place, W., April 9th, 1921.

LUNACY IN EGYPT.

To the Editor of THE LANCET.

SIR,—I notice that in THE LANCET of March 12th, p. 553, under this heading there appears the statement that "at Khanka are received the more quiet patients and no women, a rather special class." As this statement *may give a wrong* impression of the type of cases admitted nowadays to Khanka Hospital for the Insane, may I point out that the classes of cases received at the two Egyptian hospitals for the insane are as stated on p. 3 of the report under review:—

> "Abbassia Asylum receives all female cases, all criminal cases, all paying cases, and male cases arising in Cairo. Khanka Asylum receives all non-criminal pauper male cases arising in Egypt except in Cairo."

Thus the cases admitted to Khanka Hospital include all types of insanity among men.

Prior to 1917, owing to deficient means of communication, Khanka Hospital only received cases transferred from Abbassia Hospital, but since that date patients are received direct from their homes. The admissions at Khanka Hospital, therefore, comprise all types of insanity occurring amongst the population of Egypt similar to male asylums in other countries.

I am, Sir, yours faithfully,
H. W. DUDGEON,
Director, Khanka Hospital for the Insane.
March 31st, 1921.

CORPORAL PUNISHMENT IN SCHOOLS.

To the Editor of THE LANCET.

SIR,—The report of the joint conference of the Medical Officers of Schools Association with representatives of educational associations in your issue of April 2nd (p. 699) contains an inaccurate summary of my speech. I am there represented as stating that I "used two-hour periods of detention, which had resulted in corporal punishment becoming obsolete, not because it was not wanted, but because there were persons who could not be trusted with it." The inference would naturally be made that there were persons (presumably masters, though here the headmaster is the only person who may inflict corporal punishment) of the kind referred to, in this school. That is not so. What I said was (1) that I hoped that corporal punishment *generally* would eventually become obsolete, because I had heard of or come across persons in the course of my experience (both masters and "prefects") who were not fit to be trusted with the power of inflicting it; (2) that the weekly two-hour periods of detention, available only for house masters (acting on their own behalf or on reports made by class masters) have so far resulted in corporal punishment becoming unnecessary. It still remains in reserve as a final resort.—I am, Sir, yours faithfully,

GUY KENDALL,
Headmaster, University College School,
April 10th, 1921. Frognal, Hampstead.

TREATMENT OF DISABLED SOLDIERS: WORK OF THE MINISTRY OF PENSIONS.

To the Editor of THE LANCET.

SIR,—There are some members of the medical profession who are not in the way of treating disabled soldiers, but who will be interested to hear what is done for their treatment and recovery by the Ministry of Pensions, whose good work for the disabled is, besides, not sufficiently made known to the public, who only hear the complaints that are made, made often without sufficient cause. A soldier who becomes unfit for service is "boarded," a sailor is "invalided" and discharged as permanently unfit. The board fills up a treatment card for him if it thinks good, and when he returns to his home he is visited by an emissary of the Local War Pensions Committee, and is put in touch with the person or institution which can give him the treatment required. If the board has found he requires no treatment just now, but yet a little later he becomes uncomfortable and complains to his Local War Pensions Committee, it has him examined by a local medical man on behalf of the Pensions Ministry, who, if he finds the trouble is the consequence of a disability contracted in the service and due thereto, will get for him the treatment that his condition needs, medicine, appliances, massage, electrical or sanatorium treatment, or he may send him to a pensions hospital should indoor treatment be required. The pensions hospital is a large well-staffed and well-equipped institution. I have one now in mind which had 600 beds established in an emergency hospital built for the war on the sunny slope of a hill in charming surroundings. It had a medical superintendent with some eight other officers resident, and a dozen visiting specialists in surgery, medicine, X ray, ear, eye, massage, electrical, and so on, each of whom had a well-equipped department at his control; the nursing is done by the Ministry of Pensions Nursing Service, and, if I may judge by the cleanliness of the wards and the evident care of the nurses dealing with disabled patients, the work of that Nursing Service is very well performed. Officers and other ranks are received, and so far as possible cured. But more is attempted than physical cure. Reconstruction is also a prominent aim. There are workshops and schools. Men are trained as basketmakers, carpenters, mechanics, tailors, shoemakers, bookkeepers, photographers, painters, &c. They are taught how to raise and care for fowls and other farm stock. There is a capital splint-room and a workshop for making artificial limbs. They cannot be doing work all the time, they have their prescribed treatment as their first duty; the man you see as you pass with his forearm in the whirlpool hot bath would have been found, had you come in the afternoon, in the shoemakers' shop, and so on. Insane patients are not received, but there are wards for consumptives, well isolated. The men, who wear their own clothing, not uniform, appeared well-fed and happy, the staff were cheerful and good-natured, there was a good recreation-room with a small stage, and a clean, well-kept dining-room. The public would be satisfied if it knew how much thought and care is being given to the treatment and reconstruction of its disabled heroes, and I recommend others to do, as I have just done, and see over one of these centres.

I am, Sir, yours faithfully,
March 29th, 1921. D.SC.

Obituary.

J. HOPKINS WALTERS, M.R.C.S. ENG.

IN Dr. J. Hopkins Walters, who died at Reading on March 4th, at the age of 76, there passes a notable character. Dr. Walters was educated at Guy's Hospital and practised during his earlier days at Faringdon, Berks. In 1878 he moved to Reading, where he speedily became one of the leading practitioners in the town—a position which he held until his retirement in 1913. He was on the active surgical staff of the Royal Berks Hospital from 1879 to 1904, and subsequently was appointed consulting surgeon. He was President of the Reading Pathological Society for two years. In his younger days he was a keen sportsman and good shot; he also took a great interest in the Volunteers, in which for many years he was a surgeon-captain. In local politics he was prominent, sitting for a considerable period on the Reading Town Council, where he was a formidable adversary in debate and prompt in action. Temperamentally a fighter, he was not afraid of stating his views, often original and always founded on reason, in vigorous and, at times, picturesque language. Dr. Walters, though of the older school of medical men, was readily receptive of new ideas, and up to the time of his retirement was more up to date than most practitioners of his years. Even after he relinquished active practice in Reading he made a voyage half-way round the world as ship's surgeon. On the outbreak of war he volunteered for various posts which the authorities, on account of his age, were unable to grant him, and he eventually acted as medical officer to the regiment quartered in the town and to two V.A.D. hospitals. He was a good speaker and a versatile writer, both in the medical press and as a controversialist in lay journals.

On the eve of his death he had seemed in better health than usual, and, indeed, played a game of billiards at his club. Death occurred suddenly in his sleep, as he had always desired—he was ever impatient of illness in himself. Like all able men of his type, he had some enemies and very many friends.

CHARLES ALBERT HINGSTON, M.D., B.SC. LOND.

Dr. C. A. Hingston's death at Plymouth on April 5th removes a well-loved practitioner who was also a wise and generous philanthropist. Son of the late Dr. Charles Hingston, he was born at Plymouth in 1843, and after being educated locally, entered as a student at St. Bartholomew's Hospital, London, and matriculated at the London University. On graduating M.B. in 1864 he joined his father in partnership, taking his M.D. and B.Sc. degrees a year later. His public appointments included that of consulting physician to the Plymouth Public Dispensary and Dental Dispensary, and physician to the Ear and Throat Hospital, Plymouth, and to the Devon and Cornwall Female Orphan Asylum. Dr. Hingston was particularly interested in the Y.M.C.A. movement and did much to put its local branch on a firm financial basis, presid[illegible] himself over the South-Western District of the A[illegible]tion. He made himself responsible for [illegible]ding [illegible] Crownhill Convalescent Home, and he [illegible] £5000 on a lodging-house for tramps. He will be missed in and around Plymouth.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

The Medical Committee of the House of Commons.

THE Medical Committee met on April 11th at the House of Commons. The following resolution was put and passed unanimously:—

> That the medical Members of the House of Commons express their cordial appreciation of the services of the Right Honourable Christopher Addison, M.P., as Minister of Health, and congratulate him on the excellent work he has done as the first Minister in the *face of many difficulties.* They wish to place on record their admiration for his zeal and devotion to duty, and his untiring work in the interests of public health.

The Public Health Officers (Security of Tenure) Bill was discussed, and the Committee decided to lend it their support. The Coroners Bill was considered, and it was decided that when this Bill reached committee a new clause should be moved to increase the fees paid for post-mortem examination and medical evidence. The Tuberculosis Bill and the Health Estimates were then considered. The Dogs Bill was discussed, and opposition to it was agreed upon unanimously.

Public Health (Tuberculosis) Bill.

On Wednesday, April 13th, Sir A. MOND (Minister of Health) moved the second reading of the Public Health (Tuberculosis) Bill, a measure the object of which is to transfer the institutional treatment of tuberculosis from the National Health Insurance Commissioners to the County and Borough Councils. The Bill was read a second time.

HOUSE OF COMMONS.

TUESDAY, APRIL 5TH.

The Case of Dr. Denning.

Mr. MONTAGU, Secretary for India, in reply to Mr. T. GRIFFITHS, said that the new Reform Act now in force in India in no way affected the pre-existing right of a British-born subject to sue for breach of contract for personal service in India. Contracts for service under the Government of India were made with "the Secretary of State in Council." Such subject would presumably sue the Secretary of State in Council in respect of a breach either in India or in this country. The action could be brought in India or in this country, according to circumstances. The position would remain unaltered in so far as an officer certified by the India Office Medical Board to be incapacitated for further service in India was not regarded as necessarily entitled to know the medical grounds on which such a certificate was given. Such contracts were not subject to the will and pleasure of the Crown, except that the Crown had in law the right to dispense with the services of its officers, and it would not be in the power of the Secretary of State in Council, or of a Government in India, to alter the law in this respect, or to limit this right of the Crown when entering into such contracts. The Secretary of State in Council would remain the authority for the recruitment of those services which were now known as "all-India services"—such as the Indian Civil Service, the superior police service, the Indian Educational Service, and so forth—and consequently would remain the contracting parties for these. Recruitment in this country of Services, the members of which were not to be appointed and controlled by provincial governments, would probably be made over for the most part to the High Commissioner for India, and he would necessarily, subject to instructions he received from the authorities in India, for whom he was acting, have power to contract on their behalf, but in the name of the Secretary of State in Council. It would, therefore, still be open to officers like Dr. Denning to sue the Secretary of State in Council.

WEDNESDAY, APRIL 6TH.

Local Rates and Public Health.

Colonel BOWLES moved "That a Select Committee of the House of Commons be appointed to inquire into the incidence of local rating by public authorities and to make a report." The present Prime Minister, he said, when Chancellor of the Exchequer in 1911, set up a Departmental Committee on local taxation, and that Committee reported that since the time of the Royal Commission, which reported in 1901, the following expenses had been placed on the rates: National Insurance for Tuberculosis Sanatoriums, provision of meals for scholars, provision for medical inspection in schools, asylum officers' superannuation, &c. Since 1911 there had been a great many further demands upon local authorities for the Mental Deficiency Act, the Venereal Disease Act, &c. He felt that it was rather hopeless for him to attempt to indicate exactly what line the Government should take in this matter. He understood, however, that the question was receiving the attention of the Government, and he hoped that it would be dealt with promptly.

Lieutenant-Colonel Sir A. WARREN, in seconding the motion, *pointed out that if the business of the House had followed the* course set down, there would have been a discussion on the previous day on the second reading of the Public Health (Tuberculosis) Bill which was a measure to transfer the institutional treatment of tuberculosis from the National Health Insurance Commissioners to the local authorities of the country. It was estimated that the additional services under the Bill would involve expenditure out of public funds of £40,000, of which £20,000 was to be met by the Exchequer, and £20,000 from the rates. Why should this expenditure be put on the rates? Surely if there was one question that could be regarded as eminently national it was the white plague, tuberculosis. In his opinion the time had come when the question of the rates had got to be seriously considered, and when some measure of protection had to be set up for the unfortunate ratepayers throughout the country.

Mr. MYERS said the Labour Party would support the motion, but for perhaps quite different reasons from some of those which had been already advanced. The present method of assessment in respect of local rates was very largely antiquated and out of date. Take a professional man—a medical man, solicitor, architect, or a man of that kind. He occupied perhaps very small premises in a side street, and made, say, £1000 a year. The business man making a like sum was mulcted in rates out of all proportion to what the professional man had to pay, and there was no equity in an arrangement of that character. In every Act of Parliament that came through the Ministry of Health or any of those departments that had to deal with local government more and more calls were being made on the local authorities. In 1914 the average rate per head of the population in England and Wales was £1 18*s.* 11*d*; in 1919 it was £2 5*s.* 1*d.*, an increase in five years of 6*s.* 2*d.* per head. In the same period the Government grants were: In 1914 *an average per head of the population of* 12*s.* 4*d.*; and in 1919 15*s.* 1*d.*, or an increase of 2*s.* 9*d.* He suggested that at the present time local rates had nearly reached breaking point, in so far as they were imposed upon houses and similar property. He held the view that one of the sources of new revenue that they had got to tap was the *taxation of land values. The Government themselves had* reached a point when they were trying to impose upon local authorities for the purpose of reducing the rates a very undesirable policy, which in the long run would operate both against the local authorities and the community as a whole. The two circulars which had reached *the local authorities from the Ministry of Health and* the Board of Education were nothing less than a public scandal, and they moved in the direction of national suicide. To attempt to economise upon education and public health for the purpose of keeping down the rates in his judgment bordered on national imbecility, and no House of Commons ought to countenance or encourage the general principles which underlay those two circulars.

Major GRAY said it was useless for the local ratepayer to expect much sympathy from that House when he would not make the least effort at elections to see that fitting persons were returned to take part in the work of local government.

Sir A. MOND (Minister of Health) said when they looked at the increase in the rates in this country from a total sum of £71,000,000 for 1913-14 to £149,000,000 for the financial year just ended, the figures were apt to stagger one, but they had to consider the fact that the value of money had very much diminished. It was not really the case that the reason for the increase in the rates was to be found in the number of large and heavy burdens which had recently been imposed on local authorities by new legislation. The real cause was of a much more normal and automatic character. The new work which had been imposed upon local authorities by health developments—in regard to tuberculosis, venereal disease, maternity and child welfare—did not amount to more than a 2½*d.* rate throughout the country. Not that he felt that new services, even of small amounts, should lightly be thrust upon local authorities at the present time. As Minister of Health, it was his firm intention to endeavour to avoid all unnecessary expenditure in the very difficult financial circumstances in which they now found themselves. Good strict administration and the application of the best intelligences in localities to their own affairs would do more in the long run for increased efficiency and lower rating than any juggling with local taxation. He had not yet had time to go fully into the matter, but a strong Cabinet Committee had been appointed by the Prime Minister to take up the question with the purpose and intention of introducing legislation next session. He thought they would proceed more quickly on those lines than by appointing a Select Committee.

After further discussion the House divided, and the motion was negatived by 49 votes to 48. The result was received with laughter.

Royal Naval Hospital at Yokohama.

Commander BELLAIRS asked the Secretary to the Admiralty whether the Admiralty could take steps to abolish the Royal Naval Hospital at Yokohama as a needless source of expense.—Mr. AMERY replied: The Royal Naval Hospital at Yokohama is required for the reception of convalescent cases from Hong-Kong to remove them from the period of hot and damp weather experienced there. Its abolition would result in a larger number of cases being invalided home from the China station with the consequent inconvenience and expense. I am therefore unable to agree with the view of my honourable and gallant friend that the hospital is a needless source of expense.—Commander BELLAIRS: Is my honourable friend aware that though this hospital has something like 80 or 90 beds in the year 1920 not a single patient was accommodated, and the maximum number accommodated in recent years was only eight; and is it not ridiculous to have such expense maintained?—Mr. AMERY: I noticed those figures, and was struck by them, but I understand that the reason was that the hospital was not open last year at the time when patients from Hong-Kong are usually sent there; but I will inquire further into the matter and see if any economy can be effected.

Dr. Addison's New Post.

Mr. CHAMBERLAIN (Leader of the House), replying to Major KELLEY and Major C. LOWTHER, said that the Minister without portfolio received a salary of £5000 per annum. He had attached to him two civil servants drawn from the Ministry of Health. He would discharge duties analogous to those performed by Sir L. Worthington-Evans and Mr. G. N. Barnes when they held a like post. In the present pressure of public business there was definite need for a Minister of Cabinet rank unburdened by departmental duties, and the work of his colleagues in that capacity was most valuable. No time had been fixed for the duration of the appointment.

Financial Aid for the Hospitals.

Colonel MILDMAY asked the Minister of Health whether he was taking any action, in accordance with the recommendations of the Interim Report of Lord Cave's Committee, with reference to the disposal, in the interests of hospitals, of the surpluses of Approved Societies.—Sir A. MOND replied: A copy of the Report has been sent to every Approved Society with a covering letter, in which the society is urged to give its serious consideration to the question of using part of its disposable surplus (if any) in making payments towards the cost of the treatment of its members in hospitals. The right honourable and gallant Member is, of course, aware that this is only one of many additional benefits which it is open to societies to provide.

Education of an Epileptic Child.

Sir BURTON CHADWICK asked the President of the Board of Education whether he was aware that the local education authority for Barrow-in-Furness, after having tried without success to obtain a place for an epileptic child in England, had now obtained a place for that child in a certified school in Scotland; whether the Board of Education had declined to sanction contribution towards the maintenance of that child on the ground that they were precluded by law from authorising such contribution; whether, if the Board had so declined, the legal ground on which the objection was made was that the certified institution willing to receive the child was in Scotland; and whether, the Board having stated that they recognised there was at present no vacancy in any certified school in England, it was possible for the authority, under the extraordinary condition, to contribute to the educational training and care of this child in a certified school in Scotland pending a vacancy arising in a certified school in England.—Mr. FISHER replied: The institution to which the honourable Member refers is not a certified special school, and is not recognised by the Scottish Education Department. The answer to the second part of the question is in the affirmative. A local education authority in England and Wales is precluded under Section 2 of the Elementary Education (Defective and Epileptic Children) Act, 1899, from educating an epileptic child in an institution not certified by the Board.

Dr. Denning's Contract.

Mr. ROBERT RICHARDSON called the attention of the Secretary of State to the stricture of a judge on the form of contract relied upon by the plaintiff in Denning v. the Secretary of State for India and asked whether he was aware that in certain respects the new form of contract was open to similar criticism.—Mr. MONTAGU replied that assurance had been given by the Attorney-General that the judge's remarks would receive attention, and pointed out that the new contract differed from the old in stating more explicitly that services may be terminated on account of medical evidence.

Mr. THOMAS GRIFFITHS asked the Secretary of State for India whether he was aware that Dr. Denning contended that the medical evidence, upon which his contract of service had been prematurely terminated, was wrong in fact and false in deduction; inasmuch as, while the position of the India Office was that Dr. Denning had developed cardiac disease after an attack of malaria in India, his condition was consequent on rheumatic fever at the age of 14, and was present when he was passed for service in India. Further, Dr. Denning declared that an eminent medical specialist considered that functional efficiency was not impaired.—Mr. MONTAGU replied that while Dr. Denning alleged that his condition was present in 1909 when he was passed for service in India by a medical board, he (Dr. Denning) at that time had signed a specific declaration that to the best of his knowledge and belief he was not afflicted with any form of disease.

Mr. SPOOR asked the Secretary for India whether the main difference in the new and old forms of contract for service in India was to make it clear that the officer served at the will and pleasure of the Crown, but that the new form of contract contained no provision safeguarding a civil servant against injustice through departmental blunders; and whether he would consider the advisability of arranging for future cases of dispute to be referred to an independent tribunal, and so avoid departmental mistakes inadvertently ruining the careers of able men and losing their services to the Indian Empire.—Mr. MONTAGU replied: The relevant point of difference between the present form of contract and that which was in use in 1909 is that the present form states explicitly a condition, which in the earlier form was contained by reference to the Civil Service Regulations—namely, that service may be determined by reason of medical unfitness on the report of a duly constituted advisory medical board. I do not understand the honourable Member's references to departmental blunders and mistakes and do not consider it necessary to insert any provision purporting to safeguard a civil servant against their occurrence nor to take the action suggested in the second part of the question.

THURSDAY, APRIL 7TH.

Cost of Pensions Administration.

Lieutenant-Colonel ASSHETON POWNALL asked the Minister of Pensions what was the total spent by his Ministry on central administration, local committees, in his estimates for 1921-22; and what proportion such administrative expenses bore to the total sums disbursed in pensions.—Mr. IAN MACPHERSON replied: In the Ministry's estimates for the year 1921-22 provision is made for the sum of £4,386,000 for cost of administration. The sum is made up as follows: headquarters and regional establishments (other than medical), £3,052,000; local committees, £1,334,000. The total sum is approximately 4 per cent. of the amount disbursed in pensions, allowances, and treatment.

Discharged Soldiers and Heart Disease.

Mr. RAPER asked the Minister of Pensions if the sum of £46,000 had been saved in pensions and grants to discharged soldiers suffering from heart disease; and what was the nature of the medical discovery by means of which this saving was effected.—Mr. IAN MACPHERSON replied: I have no knowledge of the figure referred to in the first part of the question. A sum of nearly £4,000,000 a year is at present being paid to men who are pensioned for heart disease. Every effort is being made by the establishment of cardiological clinics with improved methods of diagnosis and treatment to restore the health of men who suffer from this complaint.

Medical Care Allowances for Veterans.

Mr. WILLIAM GRAHAM asked the Minister of Pensions whether his attention had been directed to the hardship of men disabled in former wars being denied treatment allowances for their dependents during the period of medical care in connexion with their disablement; whether such treatment allowances for dependents were accorded to men disabled in the late war, although they had married after disablement; and whether it was proposed to continue this distinction against veterans and others disabled in former wars.—Mr. IAN MACPHERSON replied: The warrants and regulations of the Ministry of Pensions make no provisions for the medical treatment of men disabled in former wars, and it is only in exceptional cases that a man would need treatment at this date for a disability incurred so long ago. The question has, however, recently been raised in connexion with certain tropical diseases and is now under consideration.

Washington Maternity Convention.

Mr. CLYNES asked the Prime Minister whether, in view of the importance of the Washington Convention on Maternity, and also of the opinion that the Draft Convention of the Washington Conference must be submitted to Parliament, an opportunity would be given at an early date to discuss the Government's policy on the convention, and also the Ministerial declaration that it was for the Government to decide whether any particular convention should be submitted to Parliament.—Mr. Lloyd George replied: In view of the great pressure of Parliamentary business, I regret that I cannot at the present time make any definite arrangements for such a discussion, and I must remind my right honourable friend that it formed the subject of a discussion on March 22nd.—Mr. Clynes: If the Prime Minister cannot at present give an assurance for an early date, can he assure us that if things improve in the next week or two he will reconsider it?—Mr. Lloyd George: We will consider it afresh; yes.

Motor Traffic Regulations.

Mr. Alfred T. Davies asked the Minister of Transport whether his attention had been called to the urgent need for codifying and simplifying the numerous regulations for motor traffic; whether any representations on the subject had been made by the police authorities; and whether he would consider the practicability of issuing such a codification of the regulations at an early date.—Mr. Arthur Neal (Parliamentary Secretary to the Ministry of Transport) replied: I would refer my honourable friend to the answer given on Feb. 24th to the honourable Member for Wallsend relating to the matters at present under consideration by the Departmental Committee on the Regulation of Road Vehicles. I am sending a copy of this answer to my honourable friend. My right honourable friend the Minister of Transport is awaiting a further report from the committee before taking any steps to promote legislation.

Salaries of Ministry of Health Secretaries.

Lieutenant-Colonel Sir Frederick Hall asked the Minister of Health what was the salary and other emoluments paid respectively to the Secretary to the Ministry of Health and the Second Secretary on the appointments originally being made; what was the date of such appointments; what were these officers being paid at the present time; and was it contemplated making any increase either in their salaries or in any other manner in the near future.—Sir A. Mond replied: The salary and bonus of the First and Second Secretaries of the Ministry of Health when the appointments were originally made were respectively: First Secretary, salary £2000, war bonus £300; Second Secretary, salary £1700, war bonus £300. The date of these appointments was July 1st, 1919. The present salaries and bonuses are as follows: First Secretary, salary £3,000, war bonus £500; Second Secretary, salary £2200, war bonus £500. These increases in scales of salary are, of course, not confined to the Ministry of Health, but were approved by the Government for that and other large Departments of State in pursuance of the Report of the Committee (Mr. Asquith, Sir James Maclay, and Lord Colwyn) appointed to advise on the salaries of the principal posts in the Civil Service. The answer to the last part of the question is in the negative.

Stafford Asylum Officials.

Mr. James Wilson asked the Minister of Health if his attention had been drawn to the action of the visiting committee of the Dudley Board of Guardians in threatening to dismiss two of its officials at the Stafford Asylum for writing to the local press; and whether he will make representations to the guardians concerned on the matter.—Sir A. Mond replied: My attention has not previously been drawn to this case, but I will make inquiries and communicate the result to the honourable Member.

Standard for Unsweetened Condensed Milk.

Mr. Grattan Doyle asked the President of the Board of Trade if he was aware of the proposed standard for unsweetened condensed milk being about 12½ per cent. below the minimum cream contents recommended by the great weight of evidence heard by the subcommittee appointed by the Minister of Health; whether this was against trade interests in this country; whether it would tend to increase unemployment here; whether he was aware that the standards proposed by the condensed milk industry, manufacturers, importers, and the trade in this country were based upon the description officially given to this article in the public Chemists' Report for many years; and whether he would use his influence with the Minister of Health to fix a reasonable standard which could be met by producers in this country, and which importers should be required to reach if they desired to trade here.—Sir Philip Lloyd-Greame replied: I am aware that the proposed standard for the minimum cream contents in unsweetened condensed milk is lower than that recommended by English makers, but I am unable to accept the various suggestions made by my honourable friend. In determining the proposed standard, consideration had to be given, not only to the interests of British manufacturers, but to those of other sections of the trade, and still more to the necessity of maintaining at competitive prices adequate supplies for the requirements of the country.

MONDAY, APRIL 11TH.

Air-space in Dartmouth Dormitories.

Mr. Rawlinson asked the Secretary to the Admiralty the minimum amount of cubic air-space per boy allowed in the dormitories at Dartmouth next term when the proposed number of 589 cadets came into residence; and whether the Admiralty had been advised by their medical advisers that the amount of cubic air-space per boy was inadequate, and that in their opinion the reception of 589 cadets at Dartmouth would lead to overcrowding, and would be dangerous to the health of the cadets.—Mr. Amery replied: Reliable information is not available as to the minimum amount of cubic air-space allowed in any one particular case, as this necessarily depends upon the configuration of the dormitories and the arrangement of the beds. The number of boys at Dartmouth during the summer term, however, is not now expected to be more than 585, and this number allows of an average of about 750 cubic feet for each boy. The variation in the different dormitories is likely to be small. While this average is slightly below what would be considered desirable in normal circumstances, the amount allowed can, in the opinion of the Admiralty, be accepted for the summer term, when the amount of ventilation possible is greater than in the winter months. For the autumn term the average amount of air-space per boy will be increased to over 800 cubic feet. The dormitories at Dartmouth are better situated than those at Osborne, as they are not on the ground floor.

Institutional Treatment of Tuberculosis.

Mr. Trevelyan Thomson asked the Minister of Health the number of county and county borough councils which had made arrangements for the institutional treatment of non-insured tuberculous persons in their areas, and the number which had not made such provision for non-insured persons.—Sir A. Mond replied: 143 of the 145 county and county borough councils in England and Wales have made arrangements for the institutional treatment of non-insured tuberculous persons, but in one case the provision so far made only extends to dispensary treatment.

After-care Committees for Tuberculous Persons.

Mr. Trevelyan Thomson asked the Minister of Health the number of county and county borough councils for which he had approved schemes for the appointment of after-care committees for dealing with insured and non-insured tuberculous persons in their areas.—Sir A. Mond replied: The schemes of 27 county and county borough councils for the appointment of committees of this kind have been approved by the Ministry of Health or their predecessors.

Accommodation at Hong-Kong Hospital.

Commander Bellairs asked the Secretary for War the maximum number of patients that could be accommodated at the Hong-Kong Military Hospital; what were the maximum and minimum numbers accommodated in 1920; and what arrangements were made elsewhere, if any, for convalescent patients.—Sir L. Worthington-Evans replied: The maximum number of patients that can be accommodated at the Military Hospital, Hong-Kong, is six officers and 160 other ranks, but only four beds for officers and 122 beds for other ranks are at present equipped. The highest number of patients accommodated on any one day during 1920 was 64 in May and the lowest number was 25 in December. I am not aware of the arrangements at present existing for convalescents in Hong-Kong, but inquiries are being made. Prior to the war the sanatorium barracks were used as a convalescent centre.

Public Health (Officers) Bill.

Sir P. Magnus introduced a Bill "to amend the law relating to the tenure of office of medical officers of health, sanitary inspectors, and inspectors of nuisances, and for other purposes." The Bill was read a first time.

TUESDAY, APRIL 12TH.

Child Adoption.

Mr. Neville Chamberlain asked the Secretary for the Home Department whether he had yet received the Report of the Departmental Committee on Child Adoption, presided over by Sir Alfred Hopkinson, K.C.; and whether the Report would be published.—Mr. Shortt replied: The answer to both parts of the question is in the affirmative.

Criminal Law Amendment Bill.

Viscountess Astor asked the Prime Minister whether, in view of the wide support throughout the country accorded to the Bishop of London's Criminal Law Amendment Bill, he could give an assurance that the Government intend to adopt it and to introduce it into the House of Commons at an early date.—Mr. Chamberlain (Lord Privy Seal) replied: I can only say at the present time that if I find that this Bill can be treated as a non-controversial measure, the Government will endeavour to facilitate its passage towards the end of the session.

Government Health Policy.

Mr. Trevelyan Thomson asked the Prime Minister whether the recent change in the post of Minister of Health indicated any variation in the Government's policy with regard to health and housing administration; and could local authorities which had undertaken the erection of dwelling-houses under The Housing and Town Planning Act, 1919, rely upon the Government fulfilling in the spirit as well as in the letter the promises made to them by the late Minister of Health with regard to their financial commitments.—Mr. CHAMBERLAIN replied: Undertakings given by the Government are not affected by changes of individual Ministers and the Government have no intention of departing from any pledges given to local authorities with respect to financial commitments entered into by them with the approval of the Ministry of Health.

Costs of the Denning Case.

Mr. THOMAS GRIFFITHS asked the Secretary for India whether he was now in a position to state the cost to the country of the legal proceedings in Denning *v.* Secretary for India, and of the time and incidental costs of India Office officials in resisting Dr. Denning's claim; and, if so, would he state the money paid out in respect of legal proceedings, the estimated cost incurred by the officials, the moneys paid to Dr. Denning, and the loss of income alleged in his statement of claim.—Mr. MONTAGU replied: The costs of the legal proceedings incurred by the Secretary of State in Council were £703 18*s.* 3*d.* As stated in answer to the honourable Member's question on March 2nd the Secretary of State in Council also paid £500 to Dr. Denning on account of the latter's costs. These sums are chargeable to Indian revenues. There was no expenditure in respect of the time and incidental costs of India Office officials. The loss of income alleged in Dr. Denning's statement of claim was £2728, including allowances.

Salaries of Health Insurance Officers.

Viscountess ASTOR asked the Minister of Health whether the scale of salaries for health insurance officers in the Ministry of Health, which was formerly £80 to £200 for men and women alike, had now been altered to £80 to £250 for men and £80 to £180 for women; and, if so, in view of the intention of the Sex Disqualification (Removal) Act, would he reconsider this.—Sir A. MOND replied: The differentiation of salaries is as stated in the question, and follows the recommendations of the Civil Service National Whitley Council Reorganisation Committee's report of February, 1920, which apply to the whole Civil Service in respect of the clerical class, with which class the Health Insurance officers have always been associated. Women appointed before the change in scales will continue to rise to a maximum of £200.

Medical News.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND.—Professor Harold Pringle and Dr. T. M. Thomson have been elected Fellows of the College.

ROYAL SANITARY INSTITUTE.—A lecture will be delivered on Wednesday, April 27th, at 5.30 P.M., by Colonel C. H. Melville, R.A.M.C., on Some Lessons of the War, at 90, Buckingham Palace-road, London, S.W. 1.

CONJOINT BOARD OF SCIENTIFIC SOCIETIES.—At a general meeting of the board held in March last it was decided to discontinue the publication of the Annual Calendar and Fortnightly Bulletin of Scientific Meetings (Diary of Scientific and Technical Societies) owing to the heavy printing liabilities incurred.

ROYAL INSTITUTION OF GREAT BRITAIN.—On Tuesday, April 19th, at 3 P.M., Professor Arthur Keith, F.R.S., will give his first lecture on Darwin's Theory of Man's Origin (in the Light of Present Day Evidence). The Friday evening discourse on April 22nd will be delivered at 9 P.M. by Sir James Walker, F.R.S., on Electro-Synthesis in Organic Chemistry.

INSTRUCTION IN HOSPITAL ADMINISTRATION: *Diploma in Public Health.*—A three months' course of lectures and demonstrations in hospital administration is being held during April, May, and June at the Western Hospital, Seagrave-road, Fulham, London, S.W., by Dr. R. M. Bruce, on Tuesdays and Fridays, at 5 P.M. The fee for the course is £3 3*s.*, payable to the Clerk to the Metropolitan Asylums Board, Embankment, London, E.C. 4.

INSTITUTE OF PHYSICS.—A meeting to inaugurate this institute will take place on Wednesday, April 27th, at 6 P.M., in the hall of the Institution of Civil Engineers, Great George-street, Westminster, London. Sir Richard Glazebrook will preside and Sir J. J. Thomson will deliver an address. Mr. A. J. Balfour is expected to be present and extend a welcome to the gathering. Non-members of the institute or of the societies associated with it may obtain tickets of admission on application to the secretary, 10, Essex-street, Strand, London, W.C. 2.

LONDON DERMATOLOGICAL SOCIETY.—A meeting of the society will be held at 4.30 P.M. on Tuesday, April 19th, at St. John's Hospital, 49, Leicester-square, London, W.C. Clinical cases will be shown by Dr. J. L. Bunch, Dr. W. Griffith, Dr. M. G. Hannay, and Dr. D. Vinrace. A discussion of the following resolution: "That the London Dermatological Society considers some form of compulsory notification for V.D. cases to be necessary," will be opened by Dr. W. K. Sibley for the affirmative, and Dr. D. Vinrace will lead the opposition.

ROYAL SOCIETY.—The papers to be read on April 21st are as follows:—Professor J. Joly, F.R.S.: A Quantum Theory of Colour Vision. Professor A. V. Hill, F.R.S.: The Energy Involved in the Electric Change in Muscle and Nerve. Mr. H. M. Kyle: The Asymmetry, Metamorphosis, and Origin of Flat Fishes, communicated by Mr. W. B. Hardy, secretary of the Royal Society. Mr. T. L. Prankerd: Studies in the Cytology of the Statolith Apparatus in Plants, viewed in Relation to their Habit and Biological Requirements, communicated by Professor W. M. Bayliss, F.R.S.

At the meeting on May 5th the Croonian lecture will be delivered by Dr. Henry Head, F.R.S., on Release of Function in the Nervous System.

POST-GRADUATE COURSE ON TUBERCULOSIS IN PARIS.—Under the auspices of the North of England Tuberculosis Society Dr. E. Rist has arranged a ten days' advanced course on tuberculosis in Paris for the latter part of May. The subjects will be treated in English, and will include artificial pneumothorax, experimental re-infection, the extent to which X ray work has affected our ideas regarding the pathology and diagnosis of lung tubercle, modern dispensary work, and so forth. One day will be spent at the Marine Hospital for Surgical Tuberculosis at Berck-sur Mer, and a visit has been arranged to Bligny Sanatorium. Special visits will also be paid to the Rockefeller Dispensaries, Pasteur Institute, Laennec Hospital, and othe institutions. All tuberculosis officers, sanatorium cians, and others specially interested in tuberc invited to participate. The fee for the course provisionally fixed at Fr.200. Further had from Dr. W. H. Dickinson, 91, New Newcastle-upon-Tyne.

National Hospital for the Paralysed and Epileptic.—A syllabus of the post-graduate courses to be held at this hospital during May and June has now been issued. Lectures and demonstrations will be given by Dr. Hinds Howell, Dr. A. Saunders, Dr. Grainger Stewart, Dr. James Taylor, Dr. Farquhar Buzzard, Dr. H. H. Tooth, Dr. Gordon Holmes, Dr. J. Collier, Dr. Risien Russell, Mr. S. R. Scott, Dr. Aldren Turner, Dr. Kinnier Wilson, Mr. P. Sargent, Dr. Russell Reynolds, and Mr. D. J. Armour. A series of six lectures and demonstrations on Neurological Ophthalmology will be given by Mr. Leslie Paton on Wednesdays, at 3.30 P.M., beginning on May 11th, if sufficient entries are received. Dr. Greenfield will give a course of lectures and demonstrations in pathology if sufficient entries are received; fee £3 3s. The fee for the post-graduate course is £7 7s., and should be paid to the secretary of the hospital. A special arrangement can be made for students who can attend one day a week only. The fee for the course in ophthalmology will be £4 4s. if taken alone, or £2 2s. if taken in conjunction with the post-graduate course. The Fellowship of Medicine's ticket will not admit to the above courses. Further information can be obtained from Dr. C. M. Hinds Howell, Dean of the Medical School, at the Hospital, Queen-square, London, W.C. 1.

Association of School Medical Officers of Scotland.—A three days' conference was held last week in the Provincial Training College, Edinburgh. Dr. A. E. Kidd, president of the association, welcomed the delegates, and Dr. John Macpherson took the chair at the first session. In his opening address he dwelt on the importance of medical examination of school children, and alluded to the problem of the mental defective. In his opinion too much distinction had been drawn between mental and physical deficiency. Mental defect was a physical disease, just as were infantile paralysis or congenital heart disease, and ought not to be regarded as a thing apart. The great need at present was for institutions and special classes where defectives could be observed and sorted out. Dr. F. C. Shrubsall, speaking on mental deficiency, dwelt on the importance of excluding physical defects before judging a child, and also of estimating the extent to which the child had had continuous education, without frequent change of school and of methods. The aim of mental testing was to ascertain the extent to which the individual was able to appreciate the nature of any problem set before him, to direct his attention to this object, to profit by previous experience, and to criticise his results. At the second session of the conference Dr. Norman Walker delivered an address on Skin Diseases in Schools; and at the third session Dr. Angus MacGillivray read a paper on the Educationally Blind Child.

Royal Institute of Public Health.—A programme of the conferences to be held from June 2nd to 4th at the Guildhall, London, has been issued. The conferences will be opened on the 2nd, at 10 A.M., by the Duke of York. At the first session Municipal Hygiene and its Suggested Connexion with the Administration of the Poor-law, and the Future of Voluntary Hospitals will be discussed. Lord Burnham will preside, and among the medical speakers will be Sir Napier Burnett, Sir Alfred Fripp, and Sir Leslie Mackenzie. At 2 P.M. the Housing Problem in its Various Bearings will be dealt with under the presidency of Sir George McCrae. The medical speakers will include Lieutenant-Colonel F. E. Fremantle, M.P., and Dr. W. G. Savage. On June 3rd, at 10 A.M., Professor Edgar L. Collis will preside over a discussion on the Necessity for Greater Attention in Industry to the Maintenance of Efficiency and the Prevention of Ill Health; the speakers will include Professor Sir Thomas Oliver, Dr. H. M. Vernon, and Mrs. R. H. B. Adamson, M.D. At 2 P.M. the subject will be the Efficiency of the Present Machinery for Dealing with Venereal Diseases and the Additional Measures Essential for Effective Prevention, with the Bishop of Birmingham in the chair. The speakers will include Professor E. W. Hope, Sir William Milligan, Professor Winifred Cullis, D.Sc., Colonel C. J. Bond, Dr. F. N. Kay Menzies, Mrs. Mary Scharlieb, M.D., Dr. J. H. Sequeira, Mrs. Marie Stopes, D.Sc., and Dr. Mary Sturge. The fifth and last session will be held on June 4th at 10 A.M., when the Efficiency of the Present Machinery for Dealing with Tuberculosis will be the subject discussed. Professor Sir Robert W. Philip will preside, and the medical speakers will include Professor S. Lyle Cummins, Professor Sir German S. Woodhead, Dr. Noel D. Bardswell, Sir Henry Gauvain, Dr. T. Hartley Martin, Dr. J. J. Perkins, Lieutenant-Colonel Nathan Raw, Dr. P. C. Varrier-Jones, and Dr. Jane Walker. Fellows, Members, and Associates of the Royal Institute of Public Health can obtain membership tickets on pplication to the secretary at the offices of the Institute. r delegates and others desirous of taking part, tickets ll be issued at one guinea each. All communications to addressed to the Hon. Secretaries, 37, Russell-square, ndon, W.C. 1.

Great Northern Central Hospital.—At the monthly meeting on April 7th the committee of management passed a resolution recording its opinion that: (a) Insured persons treated both as in- and out-patients should be paid for in full by Approved Societies; (b) payment should be made to the hospitals by the societies concerned by means of capitation grants, and not by the handing over of lump sums; (c) in view of the general public's limited opportunities of gaining knowledge of voluntary hospital questions an effort should be made to form a Voluntary Hospitals' Publicity and Propaganda Committee, towards the funds of which all hospitals should be invited to subscribe according to their number of beds and out-patients; (d) such a committee should consist of hospital representatives with some of the best publicity experts. It should endeavour to promote the interests of voluntary hospitals generally, and leave it to individual institutions to make known their particular needs.

Manchester Children's Hospital.—Owing to financial stress last year this hospital was forced to close one of its wards, thus reducing the number of beds from 180 to 150. Fortunately a grant of £20,000 from the National Relief Fund has for the time being obviated further curtailment of the hospital's services. The daily cost of each child patient is now over 7s., against 3s. in 1913.

Leicester Medical Society: Post-graduate Lectures.—A course of post-graduate lectures will be given at the Leicester Royal Infirmary on Wednesdays, at 4.45 P.M., from April 20th to May 18th. Dr. Arthur Hurst will lecture on Gastric and Intestinal Diseases on April 20th and May 4th, Dr. G. F. Still on Urinary Disorders of Childhood and Dietetic Causes of Disorders in Infancy and Childhood on May 11th and 18th, and Mr. R. C. Elmslie on Manipulative Surgery on April 27th.

West Kent Medico-Chirurgical Society.—A meeting of this society was held in the Miller Hospital, Greenwich, on March 11th, Dr. A. M. Cato presiding. Dr. Beatrice Lovibond showed a case of Spina Bifida in a girl of 17. Dr. Hildred Carlill gave a lecture on the Manifestations of Hysteria, illustrated by lantern slides. Many of these showed the cure of long-standing palsy of one or other limb, or the relief of spasms, tremors, and contractures. He contended that more disabilities of all sorts are due to mental than to physical causes, also that every one of these former could probably be prevented if its onset were witnessed by someone with the requisite knowledge and personality. Dr. Carlill set out a broad grouping of the varying types of hysterical disorder, and read the notes of a case which was treated by psycho-therapy, and which ended in tragedy. He then discussed treatment under the headings (1) preventive, (2) curative, by (a) conversation and exploration, (b) suggestion, and (c) psycho-analysis.

Royal Aberdeen Hospital for Sick Children.—The annual meeting of this hospital was held on March 28th, Sir Thomas Burnett presiding. The annual report showed that the number of cases treated during 1920 amounted to 1063 in-patients and 3008 out-patients, almost double the numbers of 1919. The ordinary expenditure exceeded the income by £2134 9s. 2d. Towards the reduction of this sum the whole amount of the legacies received, £1171 6s. 8d., has been applied, leaving a net deficiency of £963 2s. 6d., which has been cleared off by reducing the capital funds by that amount. The average daily expenditure per patient now amounts to about 5s., more than twice as much as in 1914. During the year subscriptions to the amount of £1522 15s. 7d. have been paid to the honorary treasurer for the building fund. The total amount subscribed for the building fund on Dec. 31st, 1920, was £43,162 15s. 5d. A new department has been instituted for treatment of diseases of the skin.

Exhibitions of Colour Photography.—The exhibition of the Prizma Master Pictures, held at the Alhambra Theatre, London, on April 8th, illustrated what has been achieved in natural colour photography. A series of films showed the possibilities of this new process in reproducing bowls of fruit, butterflies, gorgeous gowns, scenes on sea and mountain, and most impressively a peep into the crater of Kilaueas. The value of colour films for nature study was also well brought out in a picture representing a day with John Burroughs, a well-known naturalist. Prismatic effect was not altogether eliminated, but on the whole the exhibit evinced a high standard in colour kinematography. A second effort in colour kinematography, based on a somewhat different process, was the subject of a preliminary exhibition at the House of the Royal Society of Medicine on April 11th, when the basis of this process was illustrated by a series of medical lantern slides. The colours in this case were remarkably vivid and free from any screen effect. This exhibit was by the European Art Publishing Society, of 21, Russell-street, London, W.C.

CHELSEA HOSPITAL FOR WOMEN.—The annual general meeting of governors will be held at the hospital, Arthur-street, London, S.W., on Thursday, April 21st, at 4 P.M., the President of the hospital, the Marquess of Londonderry, presiding. A public meeting will be held at 5.30 P.M. on the same day, at the Town Hall, Chelsea, in order to urge the claims of the hospital for public support.

NORTH-EAST LONDON POST-GRADUATE COLLEGE.—A special post-graduate course will be held at the Prince of Wales's General Hospital, Tottenham, London, N., from April 25th to May 7th. This course will include the practical demonstration of modern clinical and laboratory methods of the diagnosis and treatment of disease; the exhibition of groups of cases illustrating some particular subject; a series of clinical lectures closely associated with medical practice; and demonstrations of cases at special hospitals. The fee for the course, to those not members of the Fellowship of Medicine, is 3 guineas, or 2 guineas for either week. A detailed syllabus can be obtained on application to the Dean. The lectures, at 4.30 P.M. daily, are free to qualified medical practitioners. Names of those wishing to attend should be sent, not later than April 21st, to the Dean at the hospital or to the Secretary of the Fellowship of Medicine at 1, Wimpole-street, London, W. 1.

RONTGEN SOCIETY.—A general meeting will be held on Thursday, April 21st, at 8.15 P.M., in the Physics Lecture Theatre, University College, Gower-street, London, W.C. A paper on a New Form of Stereo-fluoroscope will be read by Professor A. M. Tyndall, D.Sc., and Mr. E. G. Hill, B.Sc. A special meeting of the society will be held at Manchester on Friday, May 6th, at 8 P.M., at the University. Professor W. L. Bragg will deliver a paper and Professor A. V. Hill, F.R.S., will give a demonstration of some electro-physiological experiments. The society's exhibition will be held at the Royal Photographic Society during the whole of June. The President, Dr. Robert Knox, offers silver and bronze plaques for the best and second best collection of four prints, the work of an assistant employed at a hospital or working for a qualified radiologist, which prints must be delivered, not later than May 24th, to the Secretary, Rontgen Society Exhibition, 35, Russell-square, London, W.C. 1. The Silvanus Thompson Memorial Lecture will be delivered by Professor A. V. Hill at the next general meeting of the society on May 19th, on Electrical Instruments and Phenomena in Physiology.

BRITISH HOME FOR AUSTRIAN CHILDREN.—The historic estate of Klessheim in Salzburg has been adapted as a permanent home for children, of which the legal ownership and ultimate financial responsibility rest with "The British Home for Austrian Children, Limited"—a company not for profit—which has been formed for the purpose by the Berkshire Committee of the Save the Children Fund. Thirty children are now in residence, but once clothing and funds are forthcoming there is accommodation for 500. It is not intended to make of Klessheim a convalescent home for seriously sick or diseased children, but primarily to admit children who are under-nourished and run-down. The management committee includes a medical man, Dr. G. S. Abram, and the Vienna Executive Committee includes Miss Harriette Chick, D.Sc., Dr. Ronald Macfie, and Dr. Ferrière, with Dr. Max Winter, Dr. Josef Griez, Herr Wilhelm Ofenheim, and Professor Dr. Clemens Pirquet among the Austrian Consulting Members. Donations, particularly annual subscriptions, are invited, and should be sent either to the hon. treasurer, J. H. Simonds, Esq., Barclay's Bank, Reading, or to the office at Threadneedle House, 34, Bishopsgate, London, E.C. 2.

UNIVERSITY OF BRISTOL.—On April 7th, at the invitation of the Vice-Chancellor and the Council of the University of Bristol, representatives of the press were entertained to lunch at the Royal Hotel. The Vice-Chancellor gave an interesting survey of the steps which had led up to the appeal for funds which the University is about to make. He recalled the leading part played by Bristol in the times of the Tudor sovereigns, and gave reasons for thinking that she might yet regain the place as the second port and second city of the kingdom. Coming to present times, he reviewed the advantages enjoyed by Bristol in the matter of University provision; he enumerated the colleges from which the University had been founded, and spoke of the central and spacious site on which most of the buildings—some complete and others being built—stand, alluding to the splendid generosity of the Wills family. Much more money was needed for endowments to meet the cost of maintenance, and the Vice-Chancellor expressed the hope that this would be collected from local and private benefactors rather than received, at some cost of freedom, from the Government. After lunch a visit of inspection was paid to the University buildings, and each guest received a portfolio of finely executed drawings of the buildings actual and prospective.

DONATIONS AND BEQUESTS.—By the death of Mr. Alexander Kilgour, of South Loirston and Cove, which took place recently, important bequests fall to the University of Aberdeen and Morningfield Hospital for Incurables. The proceeds of the estate will be divided as follows: one-fifth to the Mechanics Institution, one-fifth to Morningfield Hospital, and three-fifths to the University of Aberdeen. The estate has a rental of some £2000.—The Chelsea Hospital for Women has received from the trustees of the Zunz Bequest a grant of £400 in maintenance of its Annie Zunz Wards.

THE REFORMED PUBLIC HOUSE.—The People's Refreshment House Association, Ltd., which aims at the encouragement of temperance in the use of alcoholic drinks at licensed establishments and the provision of facilities for the supply of food and non-alcoholic refreshment at such places, can prove a satisfactory year's working for 1920. The annual report to be submitted to the annual general meeting to be held at 193, Regent-street, London, W., on April 25th shows that up to Dec. 31st last the association held 165 licensed inns, of which 26 were taken over during the year. After writing off a sum for repairs, placing £5142 to depreciation reserve, and paying £2500 interest on loan stock, the amount available for disposal is £14,417 6s. 11d. The profits for 1920 were at the rate of 12½ per cent. on the share capital issued. Grants totalling £747 have been made during the year out of the public utility fund to various local institutions. It is pointed out that if the good work of the association is to expand new capital will be needed.

TELEPHONE SERVICE IN DUBLIN.—At their last meeting the President and Fellows of the Royal College of Physicians of Ireland passed a resolution protesting against the proposed increase in the charges for the telephone service in view of the progressive deterioration of the service since it came into the hands of the Post Office. At the present time no subscriber can be confident of getting a call through. At night, owing to the curfew regulations, which prohibit the public from being abroad at night, no one can employ messengers, and important messages are sometimes delayed all night. In one of the hospitals a few months ago an urgent operation case arrived during curfew hours. No message could be got through on the telephone to the surgeon on duty, and were it not that a voluntary messenger, at the possible risk of his life or liberty, undertook to convey the message on foot a life would probably have been lost. The College adds to its protest a statement that, owing to the inefficiency of the service, medical practice in and near Dublin is hampered and life and health are endangered.

MILK ORDERS.—Orders have been issued, the effect of which is to continue in force the provisions already contained in the Orders of the Food Controller with regard to milk of special hygienic quality, the addition of colouring matter and water to milk, and the reconstitution of milk. With regard to the first matter, the effect of the new Order is that licences for the sale of Grade A and Grade A (Certified) milk will be issued by the Minister of Health instead of being issued as heretofore by the Food Controller on the advice of the Minister. It will be competent to the local authority to take such steps as may be arranged in connexion with the issue of licences, and to institute proceedings in any case in which milk is sold within their area under either of the specified designations, but without a licence in that behalf. The provisions of the Order as to the addition of colouring matter or water and as to the reconstitution of milk form a supplement to the powers of the authority under the Sale of Food and Drugs Acts. The licensing of wholesale dealers in milk and the registration of retail dealers will be continued for the present by the Board of Trade as the successor of the Food Controller, the latter function being exercised through the District Commissioners. Copies of the Orders may be obtained from H.M. Stationery Office.

KING EDWARD'S HOSPITAL FUND FOR LONDON.—The annual meeting of the President and General Council of King Edward's Hospital Fund for London, to receive the accounts and report for the year 1920, was held at St. James's Palace on April 12th, H.R.H. the Prince of Wales being in the chair. Lord Revelstoke, the honorary treasurer of the Fund, presented the balance-sheet which included the items relating to the emergency distribution on July 5th last, and the distribution of surplus Red Cross Funds carried out on July 23rd through the instrumentality of the Fund. A full statement as to the general receipts having been made at the meeting of the Council on Dec. 14th last (see THE LANCET Dec. 25th, 1920, p. 1230), when the scale of ordinary awards was adopted, the treasurer said he had nothing to add in these respects, and made the gratifying
that for the year ending Dec. 31st the
enabled to provide out of income nearly
ordinary distribution of £200,000. The

from reserve, whence also came the £250,000 to meet the emergency distribution, the effect of which had been to reduce the available funds of the corporation by about one-fourth, implying a loss of income amounting to £16,000 per annum. Lord Revelstoke added that the Finance Committee were compelled to point out that such emergency distributions could not be repeated without serious detriment to the position and utility of the Fund. The account of the receipts and expenditure and the balance-sheet having been unanimously adopted, the Chairman of the Executive Committee, Lord Stuart of Wortley, moved the adoption of the report of the Council for the year 1920. The resolution was seconded by Lady Hall and carried unanimously. The Prince of Wales, who was warmly received on addressing the Council, read a message of congratulation from the King, and then referred with pleasure to the fact that Lord Cave's Committee had reported decidedly in favour of the voluntary system of hospital management. "It was," said His Royal Highness, "for the maintenance of that system that King Edward founded the Fund, and that it still exists. I think that everybody here is convinced that it is the best system both for the patients and for the public. I am very glad that the evidence has already brought Lord Cave's Committee unanimously to the same opinion." The proceedings terminated with a vote of thanks to His Royal Highness for presiding.

Appointments.

GRIFFITHS, A., M.B., F.R.C.S. Edin., has been appointed a Medical Referee under the Workmen's Compensation Act for the Sheriffdom of Stirling, Dumbarton, and Clackmannan.

HAIRE, N., M.B., Ch.M. Sydney, one of the Hon. Physicians of the Saffron Hill Maternity Centre (Holborn, Finsbury, and City Border).

HIRSCH, Capt. C. T. W., late R.A.M.C., Anæsthetist, London Temperance Hospital.

SAVAGE, A. H., M.B., B.Ch. Oxon., D.P.H., Health Officer, Kuala Lumpur, Selangor, Malay Federated States.

THOMAS, C. N., M.B., B.Ch. Cantab., Medical Officer to the Infectious Diseases Hospital at Alvington, Gloucestershire.

Seamen's Hospital Society: Hospital for Tropical Diseases, and the London School of Tropical Medicine: ROGERS, Sir LEONARD, I.M.S., Extra Physician for Clinical Research and Lecturer; CLEMESHA, Col. W. W., I.M.S., Lecturer on Hygiene of the Tropics.

Certifying Surgeons under the Factory and Workshop Acts: VISORN, C., L.R.C.P. Lond., M.R.C.S. (Clevedon); JOHNSTON, C. H. F. (Frome).

Vacancies.

For further information refer to the advertisement columns.

Bethlem.—Two Res. H.P.'s. £25 per quarter.

Bethnal Green Hospital, Cambridge-road, E.—Fourth Asst. M.O. £400.

Birmingham and Midland Homœopathic Hospital.—Res. H.S. £175.

Birmingham, Queen's Hospital.—Pathologist. £100.

Bramshott, Hants, King George's Sanatorium for Sailors.—Med. Supt. £600.

Bristol General Hospital.—H.S. £175.

Buxton, Derbyshire, Devonshire Hospital.—Asst. H.P. £120.

Capetown City.—Asst. M.O.H. £850.

Charing Cross Hospital, Agar-street, W.C.—P. in Charge Department of Radiology and Electro-therapeutics.

Chester Royal Infirmary.—Hon. S. Hon. Asst. P. Also Asst. H.S. £175.

City of London Hospital for Diseases of the Chest, Victoria Park, E.—H.P. £100.

Sheffield Royal Infirmary.—H.S.'s, H.P.'s, Aural H.S., and Asst. Cas. H.S. £150 each.

Southampton Free Eye Hospital.—Asst. Hon. Ophth. Surg.

Staffordshire General Infirmary, Stafford.—H.S. £250.

Wakefield, West Riding Asylum.—Jun. Asst. M.O. £400.

Warwick Union.—M.O. £100.

West London Hospital, Hammersmith-road, W.—Cas. O. £5 5s per week.

Wigan Infirmary.—Hon. S.

York County Hospital.—H.S. £200.

The Chief Inspector of Factories, Home Office, S.W., gives notice of a vacancy under the Factory and Workshop Acts at Burton-upon-Trent.

Births, Marriages, and Deaths.

BIRTHS.

READE.—On April 9th, at New End Hospital, Hampstead, the wife of Dr. Arthur G. L. Reade, O.B.E., of a son.

RUSSELL.—On April 10th, at the Little House, Gerrard's Cross, the wife of Trevor C. Russell, M.B., of a daughter.

SHOWELL-ROGERS.—On April 9th, at Nottingham-place, W., the wife of E. N. Showell-Rogers, M.B. Cantab., of a son.

WOODWARK.—On April 11th, at 4, Harley-street, W., to Hilda (née Robinson), wife of A. S. Woodwark, C.M.G., C.B.E., M.D., F.R.C.P.—a son.

MARRIAGES.

GRIFFITH—VISICK.—On the 11th April, at Lyndhurst-road Church, Hampstead, by the Rev. Dr. R. H. Horton, John Richard Griffith, F.R.C.S. Eng., son of Arthur F. Griffith and Mrs. Griffith, of 59, Montpellier-road, Brighton, to Elsie Maud Visick, M.R.C.S., L.R.C.P., daughter of Dr. and Mrs. Hedley C. Visick, of 35, Rosslyn-hill, Hampstead.

DEATHS.

DUNCAN.—On April 6th, at Park House, Croydon, Peter Thomas Duncan, M.D., in his 73rd year.

MINNS.—On April 6th, the result of a motor accident, Captain Allan Noel Minns, D.S.C., M.C., R.A.M.C., Alexandra House, Thetford, Norfolk.

TAYLOR.—On April 7th, at Lovelace Lodge, Surbiton, Arthur Sneyd Taylor, M.D. Cantab., F.R.C.S., after a short illness.

WRIGHT.—On April 2nd, accidentally drowned on Summer Lodge Moor, Swaledale, Yorkshire, Joseph Farrall Wright, M.R.C.S., L.R.C.P., of Chorley New-road, Bolton, in his 56th year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

SOCIETIES.

ROYAL SOCIETY, Burlington House, London, W.

Thursday, April 21st.—Papers:—Prof. J. Joly: A Quantum Theory of Colour Vision.—Prof. A. V. Hill: The Energy Involved in the Electric Change in Muscle and Nerve.—Mr. H. M. Kyle: The Asymmetry, Metamorphosis, and Origin of Flat Fishes (communicated by Mr. W. B. Hardy, secretary of the Royal Society).—Mr. T. L. Prankerd: Studies in the Cytology of the Statolith Apparatus in Plants, viewed in Relation to their Habit and Biological Requirements (communicated by Prof. W. M. Bayliss).

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, April 19th.

SECTION OF THERAPEUTICS AND PHARMACOLOGY: at 4.30 P.M.

Annual General Meeting—Election of Officers and Council for 1921-1922.

Papers: Sir Leonard Rogers: Treatment of Leprosy and Tuberculosis with *Sodium Gynocardate*.

Dr. R. R. Walker: The Action and Uses of Kaolin in the Treatment of Asiatic Cholera.

Section of Tropical Diseases and Parasitology.—Members of this Section are cordially invited to attend the *above meeting*.

SECTION OF PATHOLOGY: at 8.30 P.M.

Annual General Meeting—Election of Officers *and Council for* 1921-1922.

Communications: Sir Lenthal Cheatle: Parenchymatous Inflammation of the Breast.

Mr. A. T. Glenny, Miss K. Allen, and Dr. R. A. O'Brien: (1) Schick Reaction; (2) Diphtheria *Prophylactic Immunisation* with Toxin Anti-toxin Mixture.

Dr. E. H. Kettle and Dr. Joan Ross: A Contribution to the Study of the Endotheliomata.

Wednesday, April 20th.

SECTION OF HISTORY OF MEDICINE: at 5 P.M.

Papers: Dr. T. Wilson Parry: The Prehistoric Trephined Skulls of Great Britain, with Description of Operations Performed.

Dr. F. G. Chandler: The History of the Diagnosis and Treatment of Empyema.

Thursday, April 21st.

SECTION OF DERMATOLOGY: at 5 P.M. (Cases at 4.30 P.M.)

Cases: Dr. Parkes Weber: A Condition Somewhat Resembling Lupus Pernio in a Child.

Dr. MacCormac: (1) Extensive *Rodent Ulcer Treated by* Massive Dosage of Radium; (2) Granuloma Annulare.

Other cases will be shown.

Friday, April 22nd.

SECTION OF STUDY OF DISEASE IN CHILDREN: *at 5 P.M.* (Cases at 4.30 P.M.)

Cases: Mr. C. Max Page: A Case of Renal Dwarfism.

Other cases will be shown.

SECTION OF EPIDEMIOLOGY AND STATE MEDICINE: at 8.30 P.M.

Paper:

Dr. W. M. Willoughby: Collated Experiences of Plague on Ships.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.

Monday, April 18th.—8 P.M., *Cantor Lecture (II.)*:—Dr. S. J. Lewis: Recent Applications of the Spectroscope and the Spectrophotometer to Science and Industry.

Wednesday.—8 P.M., Sir James Cantlie: (1) Thomson's Apparatus for Armless Men; (2) X Ray Motor Ambulance Service for the United Kingdom. (The Thomson Machine will be exhibited and its uses demonstrated by an armless man.)

Friday.—4.30 P.M., Sir George Birdwood Memorial Lecture:—*Lt.-Col.* Sir *Edward* W. M. Grigg: The Common Service of the British and Indian Peoples to the World.

LONDON DERMATOLOGICAL SOCIETY, St. John's Hospital, 49, Leicester-square, W.C.

Tuesday, April 19th.—4.30 P.M., Pathological *Specimens*. *Cases* sent for Consultation. Clinical Cases will be shown by Dr. J. L. Bunch, Dr. W. Griffith, Dr. M. G. Hannay, and Dr. D Vinrace. Discussion on the following resolution: "That the London Dermatological Society considers some form of compulsory notification for V.D. cases to be *necessary*," to be opened by Dr. W. K. Sibley for the affirmative and Dr. D. Vinrace for the negative.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

Museum Demonstrations in the Theatre of the *College for* Advanced Students and Medical Practitioners:—

Monday, April 18th.—5 P.M., Prof. Shattock: Myxoma; Chondroma.

Friday.—5 P.M., Prof. Keith: Microscopic Structure of the Colon in Health and Disease.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

Monday, April 18th.—2 P.M., Dr. S. Pinchin: Medical Out-patients. Dr. Simson: Diseases of Women. 2.30 P.M., Dr. A. Saunders: Visit to Medical Wards. Mr. Baldwin: Visit to Surgical Wards.

Tuesday.—10 A.M., Mr. Steadman: Dental Department. 2 P.M., Dr. *Burnford*: Medical Out-patients. Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. 2.30 P.M., Mr. Addison: Visit to Surgical Wards.

Wednesday.—10 A.M., Mr. MacDonald: Genito-Urinary Department. 2 P.M., Mr. D. Armour: Visit to Surgical Wards. Mr. Sinclair: Surgical Out-patients. Mr. Gibb: Eye Department.

Thursday.—2 P.M., Mr. B. Harman: Eye Department. Mr. MacDonald: *Surgical Out-patients*. Mr. *Baldwin*: *Orthopædic* Department. Mr. D. Armour: Operations.

Friday.—10 A.M., Dr. Robinson: Gynæcological Operations and Visit to Wards. Dr. McDougal: Electrical Department. 2 P.M., Mr. T. Gray: Surgical Out-patients. Dr. Morton: X Ray Department. *Dr. Pernet: Skin Department.* 2.30 P.M., Dr. Pritchard: Visit to Medical Wards.

Saturday.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 2 P.M., Dr. Owen: Medical Out-patients.

Daily:—10 A.M. Ward Visits. 2 P.M., In-patient, Out-patient *Clinics and Operations.*

ST. MARYLEBONE GENERAL DISPENSARY, 77, Welbeck-street, Cavendish-square, W.

Post-Graduate Course on Infant and Child Welfare.

A Course of Twelve Practical Demonstrations on the Management and Feeding of Infants and Young Children by Dr. E. Pritchard to Qualified Practitioners.

Tuesday, April 19th.—10.30 A.M., *Demonstration V., The* Modification of Milk.

Thursday.—3 P.M., Demonstration VI., The Uses of Dried Milk and Patent Foods.

ROYAL INSTITUTION OF GREAT BRITAIN, Albemarle-street, *Piccadilly*, W.

Tuesday, April 19th.—3 P.M., Lecture (I.):—Prof. A. Keith: Darwin's Theory of Man's Origin (in the *Light of Present* Day Evidence).

Friday.—9 P.M., Discourse:—Sir James Walker: Electro-Synthesis in *Organic* Chemistry.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

Tuesday, April 19th.—4.30 P.M., Lecture:—Mr. J. P. Buckley: Intussusception.

Communications, Letters, &c., to the Editor have been received from—

A.—Dr. H. el Arculli, Liverpool; Dr. R. E. Apperly, Lond.

B.—British Homes for Austrian Children, Lond., Sec. of; Mr. C. W. G. *Bryan, Lond.*; Dr. M. I. Notes, Short Comments, and Answers to Correspondents.

DISEASES DESCRIBED BY MEDICAL MEN WHO SUFFERED FROM THEM.[1]

BY SIR HUMPHRY ROLLESTON, K.C.B., M.D CAMB., F.R.C.P. LOND.
EMERITUS PHYSICIAN, ST. GEORGE'S HOSPITAL SENIOR PHYSICIAN, VICTORIA HOSPITAL FOR CHILDREN.

IN the selection of a subject in response to your complimentary invitation it was obviously unwise to encroach on those aspects of medicine that your teachers deal with so much more advantageously, and I have accordingly chosen one on which it is to be hoped that none of them—though here I am not on safe ground—are personally competent to speak with real authority—namely, diseases described by medical men suffering from them. Stephen Paget, in his delightful *Confessio Medici*, says: "You cannot be a perfect doctor till you have been a patient; you cannot be a perfect surgeon till you have enjoyed" (and he goes on to emphasise his choice of this verb) "in your own person some surgical experience." According to this line of reasoning the perfect author should be a man of many joys (or sorrows?); and though I wish them well it is not this kind of joy that your teachers deserve.

Victims to Their Specialty.

Although the title, "Diseases Described by Medical Men who have Suffered from Them," excludes the examples of medical men who have paid particular attention to a disease and eventually fallen a victim to their specialty, a brief reference to this subject may perhaps be made. It has been said, possibly inspired by the attractive speculation that auto-suggestion is at work, that this sequence is common, and Sir William Hale-White tells me that Sir Samuel Wilks, who was a doctors' doctor, was firmly convinced of this association. On the other hand, this coincidence is so striking that there is a risk of exaggerating its frequency. Writers of complete text-books would of necessity swell this category and must therefore be disqualified. For example, Nothnagel died of what has from the toll it levies been called the doctors' disease—namely, angina pectoris—on which he was a recognised authority; but he was also the editor of a voluminous encyclopædia of medicine, and wrote on a number of other subjects. As examples of authors unconscious that the future would add a grim personal interest to their favourite professional subjects the following may be quoted: Laennec, who died from pulmonary tuberculosis; Sir William Gull, who, with H. G. Sutton, described arterio-capillary fibrosis, from cerebral hæmorrhage; Mikulicz from carcinoma of the stomach; S. O. Habershon, the author of a book on Diseases of the Stomach, of simple gastric ulcer; G. R. Fowler, an American surgeon, author of a "Treatise on the Appendix," and originator of the Fowler position, of appendicitis; Corvisart and Lancisi of heart disease.[2] The late Sir A. B. Garrod, who wrote in 1876 that, unlike Sydenham, he could not from personal experience describe the sensations of gout, became its victim, when 70 years of age, so his son the present Regius professor of medicine at Oxford tells me. Trousseau, whose clinical lectures covered nearly the whole field of medicine, pointed out that if thrombosis occurred in a case of gastric disease, carcinoma might safely be diagnosed; when himself ill he was visited on Jan. 1st, 1867, by his former pupil Peter, who, when thus calling to express good wishes for the New Year, had the painful experience of hearing his teacher say: "It is all up with me, the appearance of a patch of phlebitis last night leaves no loophole for doubt as to the nature of my illness." Trousseau was right in applying his diagnostic deduction to his own case; he lingered on for six months, dying at the age of 66 years on June 23rd, 1867.

Occupational Diseases among Medical Men.

Attention may be called to examples of what might be called occupational diseases among medical men; medical officers specially interested in infectious diseases, including tuberculosis, syphilis, and tropical affections, on which they may have written, are naturally liable to contract these diseases, and radiologists have suffered much in the past, especially from carcinoma. Those who have worked at the laboratory aspects of infections may fall victims to these diseases, and many examples might be given. Probably the best known are those cases in which the accident has rapidly proved fatal and so do not come under the category of those who have described the disease from personal experience. But of these martyrs to medical research the names of a few may be mentioned:—enteric fever: Allen MacFadyen, H. J. Tylden, L. Jenner; yellow fever: W. Myers; Rocky Mountain fever: T. B. McClintic; plague: Müller; spirillum fever: J. E. Dutton; glanders: J. H. Wells (1909). Another group contains those who have deliberately inoculated themselves with infective or probably infective material; thus J. W. Lazear allowed mosquitoes to bite him and by his fatal illness proved the transmission of yellow fever; the late Dr. P. T. Manson allowed infected mosquitoes to bite him, and by thus contracting malaria proved that they transmitted the disease; his death, however, was due to an independent accident; the late Dr. R. Cory, of St. Thomas's Hospital, frequently vaccinated himself with vaccine lymph from syphilitic infants and eventually became infected; and John Hunter[3] inoculated himself with pus from a case of gonorrhœa but developed syphilis, and was thus led to believe in the unity of venereal disease; it is, indeed, probable that his dramatic death from angina pectoris was due to syphilitic aortitis.

Great Names Connected with Special Diseases.

Bright, Addison, and Hodgkin—the great triumvirate of Guy's Hospital—did not suffer or die from the diseases so inseparably connected with their names. Bright died at the age of 69 after four days' illness attended with hæmatemesis, and the necropsy revealed pure aortic stenosis with healthy kidneys. He was known to have some cardiac affection, but it is said that inquisitive attempts to find out its exact nature were always frustrated by him; at consultations between several eminent physicians, including Bright, the problem was sometimes attacked by proposing to compare the patient's pulse with that of a presumably healthy man (Bright); but the erudite touch of the inquiring colleague was always skilfully evaded. About Addison's end kindly reticence drew a veil at the time of his death, but it appears that he became insane and jumped out of a window at Brighton when 67 years old. Hodgkin, who was pathologist, but never on the medical staff of Guy's Hospital, died of dysentery at Jaffa at the age of 68. Dr. Joseph Ignatius Guillotin (1738–1814), who was a zealous advocate of vaccination and the founder of a short-lived Académie de Médecine in Paris, did not, as poetic justice might well demand, have his head removed by the instrument to which his name is attached.

When giving descriptions of diseases from which they may happen to have had personal experience some writers record their own sensations under a modest periphrasis such as "a man known to us ...... whose heart stands work well in all other respects but in whom intermittence of the heart may occur for many days if he remain for an hour or two with many smokers. He dare not sit in a close smoking room or in a smoking carriage." Or "a case is known to the writer in which the patient suffered from a severe attack 18 years from the onset of the disorder (bilharziasis), which had been in abeyance for some years." The late L. G. Guthrie,[4] à propos of ophthalmic migraine, wrote: "In one case known to the writer permanent paralysis of the ocular sympathetic appears to have been the result of repeated migraine."

The accurate observations of medical men on their own diseases, in spite of the quip that "he has a fool for his patient," are interesting human documents, and may add to our knowledge of the earliest indications of disease. Such personal descriptions are of special value from the point of view of the subjective manifestations or symptoms as opposed to physical signs. The physical signs are best observed by the onlooker and may escape the attention of the patient. Thus L. P. Mark, for some 15 or 20 years, each day when he looked into the glass to brush his hair or to shave had a typical acromegalic literally staring him in the face,[5] as had been clear to his professional friends for years, and when 49 was spotted in a crowd by Professor Pierre Marie, who originally described the disease, while in London for a medical entente cordiale. His graphic account of his sensations and sufferings, on the other hand, give much fresh information, especially as regards the occurrence of exacerbations in the disease, or of periods which he calls the acromegalic state during which the symptoms, like the physical signs, are accentuated; these symptoms varied from malaise to complete incapacity to do anything and mental depression.

Julius Thomsen's[6] description (1876) of the disease of the muscles (myotonia congenita) *hereditary* in his family first drew attention to this disease. This is the best, if not the only, example of a disease first brought to our knowledge by a sufferer, for it is not certain that John Bostock gave the first account of hay fever. Otherwise the nearest approach to such an original document is probably that by Dr. R. Druitt,[7] who gave a full description, especially as regards the early symptoms, of paroxysmal hæmoglobinuria under the title Paroxysmal Hæmatinuria in 1873, a year after the disease had compelled him to retire from active practice. But as far back as 1831 Elliotson[8] briefly referred to a case as connected with malaria, and in 1865, at the same meeting (on May 9th) of the Royal Medico-Chirurgical Society, G. Harley[9] and W. H. Dickinson[10] read papers on intermittent hæmaturia; Harley recognised that the red blood corpuscles were dissolved, but he believed that the underlying factor was hepatic derangement, apparently on account of the accompanying icteric tint; Dickinson, on the other hand, more nearly approached our present views in saying that we must be content to regard the disorder as something *sui generis* and the blood itself as the seat of the primary change. Druitt's symptoms began when he was 52, six years before his account of the disease was published, and lasted until his death in 1883 at the age of 68; he was the author of a once well-known handbook, "The Surgeon's Vade Mecum," which went through 11 editions.

Migraine, Asthma, and Gout.

The diseases most often described by medical patients are naturally those of a chronic character, and especially those with intervals of fair health between acute attacks of paroxysms, such as migraine, asthma, and gout.

Migraine, or sick headache, has the distinction of having been portrayed by more distinguished victims than has any other disease, even gout, and it is noteworthy that some of the most careful accounts of the visual phenomena have been given, not by medical men, but by the leading lights of pure science, especially astronomers, such as Sir G. Airy, Sir John Herschell, Sir D. Brewster, and Sir C. Wheatstone. In 1886 Hilton Fagge wrote: "I do not know of any other malady which within the present (XIXth) century has been the subject of two papers admitted into the Philosophical Transactions, as well as of communications to the Philosophical Magazine and other scientific publications in this country and abroad." It may therefore be said of it, as Sydenham feelingly remarked of gout, that it attacks more wise men than fools. Among well-known medical contributors to the literature of the disease are W. H. Wollaston, interim President of the Royal Society in 1820, who, however, threw up the profession in disgust when he was rejected as a candidate for the post of physician to St. George's Hospital in 1800; John Fothergill, the Quaker physician and philanthropist, of whom Benjamin Franklin said, "I can hardly conceive that a better man has ever existed"; Caleb Hillier Parry, the "distinguished old Bath physician"; Dr. E. Liveing, who wrote a classic on megrim (1873), Sir Samuel Wilks and Dr. Alexander Haig, a life-long sufferer until he dieted himself. Dr. Hubert Airy and Sir James Mackenzie have published coloured representations of their own spectra. Mackenzie mentions that the scintillations once came on when he was about to operate on a case of appendicitis, but in the concentrated attention given to the operation they disappeared, only to return about a quarter of an hour after the operation was finished.

Asthma and hay fever, being examples of toxic idiosyncrasies on which Dr. John Freeman has thrown the light of the laboratory, may be considered together. In 1819 John Bostock,[11] later Vice-President of the Royal Society, described his own case as a "periodic affection of the eyes and chest," and nine years later, now under the new name "Catarrhus aestivus, or summer catarrh," was able to collect 28 examples of a similar nature, but the only reference to a previous description of the disease that he could find was one by Heberden. But asthma, which it must be admitted is a rather vague term, as it may include many causes of dyspnœa, was previously well known. Thus Sir John Floyer described his own case in his "Treatise on Asthma" (1698); and in Hutchinson's Biographia Medica (1799) it is stated that John Arbuthnot's "Essay on the Effects of Air on Human Bodies" (1733) was apparently the outcome of consideration of his own case, "*an asthma which gradually increasing with his years became shortly after unmanageable and incurable.*"

Arbuthnot, in his political skit "The History of John Bull," originated this familiar personification of the English nation: "Bull in the main was an honest, plain-dealing fellow, choleric, bold, and of a very inconstant nature." It may be added that in one of his lighter touches the late Sir Victor Horsley described our three British institutions—*John Bull, Father Christmas*, and King Henry VIII.—as examples of fatty degeneration due to chronic alcoholism.

Another instance, certainly interesting on account of the correspondents, is to be found in a letter written from York on June 3rd, 1795, by Dr. Thomas Fowler (1736–1801) whose name is so familiar in Fowler's solution (liquor arsenicalis) to Dr. William Withering, of Birmingham, the introducer of digitalis, detailing his symptoms as those of angina pectoris and asking for advice; Dr. Withering endorsed the letter with his opinion that the disorder was spasmodic asthma. Turning now to later authorities, Hyde Salter wrote a treatise on asthma in 1859; C. H. Blackley, in his monograph (1873) on Catarrhus Aestivus or Hay Fever, refers to T. Wilkinson King, G. T. Gream, and W. P. Kirkman as fellow sufferers, and Trousseau[12] described his own experience; W. E. Steavenson in his published thesis for the M.B. at the University of Cambridge (1879), says, "I have never been prevented by an attack of asthma from going in for or completing any examination; but when completed and the strain on my mind relieved, it has always been followed the succeeding night and day by a severe attack."

Many famous medical men have suffered from *gout*, and some of them have made their experiences public. Thomas Sydenham (1624–1689), the English Hippocrates, was a chronic victim of gout, and towards the end of his life, when suffering from renal calculus and hæmaturia, brought out his Tractatus de Podagra et Hydrope (1685) Benjamin Franklin (1706–1790) was also plagued with gout and vesical calculus and wrote a curious pamphlet "A Dialogue between Franklin and the Gout." Dr. William Stukeley (1687–1765), not only a distinguished physician, but so eminent in archæology and druidical history that his friends familiarly spoke of him as the "Arch-Druid of this age," became so overpowered by the fatigues of his profession and repeated attacks of gout that he turned his thoughts to the church and was appointed to the living of All Saints, Stamford, in 1730, where he was treated by Dr. Rogers with his oleum arthriticum. The successful result of this external application induced Stukeley to publish "A Treatise on the Cause and Cure of Gout, with a New Rationale" (1734). It should, however, be noted that in addition to rubbing on the oil Stukeley adopted a proper regimen and left off the use of fermented liquors. A famous example of a physician recounting his own ailments is that of George Cheyne, who described his obesity, neurasthenia, and hyperchlorhydria and his cure in "The English Malady" (1733). In "An Essay of the True Nature and Due Method of Treating the Gout" (1720) he also drew on his own experience.

The late Sir Robert M. Simon suffered from *Ménière's disease*, and a graphic description of his symptoms from his own hand was published posthumously.[13]

Sir George Murray Humphry of Cambridge, had *phlebitis* on three occasions—in 1843 after right-sided pleurisy, in 1846 after typhoid fever, and again in 1851 after pleurisy. He laughed at those who kindly told him that he would die, and wrote his M.D. thesis on "The Formation of Clots in the Venous System during Life,"[14] recording his own case: "My attention was first called to it by its occurrence in a member of the medical profession, a delicate man."

Other Diseases, Infections, and Accidents.

Alimentary canal.—Merycism or rumination has been described by several medical sufferers: Näcke, Cambay, Blanchard, and Halliday.[15] J. H. Keay,[16] from frequent personal experience, insisted that the initial pain of *biliary colic*, presumably due to the entrance of a stone into the cystic duct, is felt in the back and *not*, as is commonly stated, in the right hypochondrium or epigastrium, and Dr. Kraus, of Carlsbad, expressed the same opinion on similar grounds. Professor Lewellys Barker,[17] in an article on the diagnosis of gall-bladder disease, mentions that when 8 years old he had enteric fever, and that 35 years later four gallstones giving cultures of *B. typhosus* were removed from his gall-bladder. Dr. E. A. Cockayne[18] detailed his own experience of catarrhal jaundice.

Cardiac and renal disease.—The late Sir W. T. Gairdner, who wrote much on the cardio-vascular system, gave an account[19] of his own symptoms in Stokes-Adams's disease. W. C. Wells (1757–1817), the famous author of "The Essay on Dew," suffered from dropsy and cardiac asthma; he wrote on scarlatinal and other forms of dropsy, pointed out that the urine contained albumin in scarlatinal and cutaneous dropsy, but not in primary hydrothorax or ascites. He noted that in some of his cases the kidneys were diseased, and thus prepared the way for Bright's generalisation; he anticipated Blackall, who subsequently elaborated the observations on the presence of albumin in the urine. James Jurin (1684–1750), the first physician to Guy's Hospital (1725-1732), suffered severely from renal calculus, and described his painful experience in his "Account of the Effects of Soap-Lye, taken Internally, for the Stone," published in 1740.

Infections.—Murchison, who had typhus twice, graphically described his own sensations and delusions during the delirium of the disease, and quoted similar personal accounts by Hildenbrand and Gueneau de Mussey. Benjamin Rush, "the American Sydenham," after advocating bleeding and purgation with good results in yellow fever, contracted the disease, had his own treatment, and recovered. Surgeon-General G. M. Sternberg, who investigated many outbreaks of yellow fever, and wrote much, especially about the ætiology and prevention of the disease, had an attack after the third outbreak and was as energetic as ever in advocating measures for its prophylaxis. Sir James Paget in his account of his illness contracted from examination of a patient dead of pyæmia remarked, "Sir William Lawrence used to say that he had not known anyone to recover on whose case more than seven had been consulted. Our art has improved. I had the happiness of being attended by ten." In recording his own experiences as a case of staphylococcic infection Sir Lauder Brunton[20] noted that the pain was worse after meals, when hydrochloric acid was being absorbed from the stomach, and that relief followed the ingestion of sodium bicarbonate and its local application to the pustule; he referred to the diminished alkalinity of the blood, but did not use the term acidosis, which, though invented, was not then in popular parlance. Alexander Ramsay (1754-1824) who, according to some, was a compound of personal deformity, immense learning, uncontrollable temper, and inordinate vanity, wrote "Personal Experiences from the Bite of a Rattle-snake."[21]

Tuberculosis has naturally attracted its medical victims to its study, and has recently been responsible for a number of medical officers to sanatoriums. Sir Andrew Clark, when young, was gravely ill with tuberculosis, and when given an appointment at the London Hospital in 1853 was not thought likely to survive a year; no doubt his own condition led him to undertake inoculation experiments with tuberculous material, a subject to which Villemin's researches were then (1865) calling much attention; but his work was interrupted by an attack of hæmoptysis. He also did much to establish the existence of a non-tuberculous destructive disease of the lung under the name of fibroid phthisis or, as it is now called, chronic (interstitial) pneumonia. E. L. Trudeau developed pulmonary tuberculosis in 1871 and was the pioneer of the open-air treatment of the disease at his sanatorium at Lake Saranac, in the Adirondacks, where R. L. Stevenson was for a time, and where, according to E. V. Lucas[22] simplified spelling is in vogue and "that most august and mysterious of the functionaries of life, the physician, is able to watch his divinity dwindle and his dignity disappear under the style Fizisn." Dr. James Hughes Bennet went to Mentone for disease of the lungs and was the chief agent in establishing Mentone as a health resort; he wrote a book on "The Treatment of Pulmonary Consumption by Hygiene, Climate, and Medicine."

Rupture of his tendo Achillis about 1762 led Alexander Monro, primus (1697-1767) of Edinburgh, to record his accident; and John Hunter's similar experience while dancing in 1768 inspired him to investigate experimentally the healing of tendons in dogs. Percivall Pott's fracture, due to a fall from his horse in 1756, has kept his name in perpetual recollection.

Lastly, most of the writers on old age and its infirmities, such as Cornaro, Sir Anthony Carlisle, Charcot, Sir George Humphry, Sir Hermann Weber, and Dr. R. Saundby, have been approaching the sere and yellow. A few dying physicians have recorded their experience until the pen slipped from their fingers, and it is difficult to find a more comforting last word than that of the great William Hunter, "If I had strength enough to hold a pen, I would write how easy and pleasant a thing it is to die."

HEALTHY FEET.

ON April 6th a lecture on "Healthy Feet" was delivered at the Institute of Hygiene by Mr. W. H. Trethowan, who said that during and after the war, as surgeon to one of the great military orthopædic hospitals, he had had an extended opportunity for noticing how frequently deformities and disabilities of the feet contributed to the C3 element enrolled in the new army, and also the effect of these foot conditions on active service. A great number of cases of so-called "trench feet" were reported, but when, from the cases thus grouped, those really due to frost-bite were eliminated, the remainder were ordinary mechanical disabilities common in civil life, such as flat-feet, too arched feet, clawed toes, hammer toes, and similar troubles. Apart from frost-bite, he had never been able to convince himself that such a disease as trench feet existed.

It was, he continued, impossible to find in a civilised adult a perfect foot—one of ideal shape, which would do its work properly and gracefully, and give no trouble. To keep the feet healthy it was necessary to "catch them early," and the most effective work for reform can be carried out by the provision of proper footwear for children. Growing children must not be on their feet all day long, and should not be required to follow laborious occupations, entailing heavy lifting. Standing about was more harmful than prolonged vigorous walking, and in any collection of women, such as nurses, who had to stand about during their work, foot troubles were numerous.

Flatness and Falling-in of Foot.—Height of Heels.

Flat-foot was the commonest of such troubles. But generally, and nearly always in children, the first trouble was not really flat-foot—that is, a giving way of the long arch—but a falling-in of the foot, just below the ankle-joint, a condition often referred to as weak ankles, leading to more strain on the inner border of the foot, and, later, to the arch itself giving way. The best exercise for flat or weak foot was correct walking, developed until it becomes automatic. Slight turning out of the toes was correct when standing easy, but in walking the feet should be kept parallel. The essential use of a boot was to protect from over-strain the ligaments which bind the small bones together, and consequently the boot or shoe should correspond to the shape of the foot. Instead of the shoe fitting the foot, however, it was unfortunately the case that the foot is compelled to adopt the conventional standard shape of the shoemaker, narrower than the actual human foot, producing a pointed toe portion in which the great toe was cramped, turned outwards, and not permitted to move. So-called squared toes were a delusion and a snare; it was not the part projecting beyond the toes which mattered, the important point being that none of the toes must be subjected to side pressure. A good shoe should also have a well-curved and stiffened waist.

With regard to heels, Mr. Trethowan said the Cuban was the most satisfactory for general use, the Louis heel being bad on account of its curved mechanical shape and inefficient support, and also because it weakened the whole sole of the shoe. In a strong foot the lower, brogue heel could be used. Children with normal feet did not require much heel. Women, however, favoured high heels, and, while there was no doubt that some did so for purely cosmetic reasons, it was certain that the majority of women wore high heels as a response to the relief afforded to the ligaments of the foot. Women, being hampered by skirts, could not get such freedom of movement in the hips as men are able to do, and it might be from this cause they needed the more efficient support afforded by heels. The action of the foot in man was not nearly so marked as in women, as men propelled themselves with the hip movement of long strides, while women walked more with their feet. It was a universal and traditional idea that the majority of troubles occurring in the feet are the evil results of the use of heels, but the anatomy and movements of the foot showed fully that the strain on the long arch must lessen in proportion as the heel is raised; this was the experience of the vast majority of women, in spite of medical advice to the contrary. The most important measure in giving relief in cases of weak or overstrained feet was to raise the height of the heels, and not to lower it, as was nearly always advised. The height of the heel for remedial purposes should not exceed 2¼ inches, and in house-shoes should not be less than 1¼ inches. Naturally, the height should do no more than afford relief. In cases of overstrained feet slippers must be avoided. Heels not less than 1¼ or 1½ inches in height were suitable for general use in healthy feet.

Selection of Footwear.

Most ready-made boots, Mr. Trethowan said, failed miserably in the support afforded to the inner border of the foot, and this fact, together with waists that are thin and unyielding, and which bulge downwards after use for two or three weeks, was largely responsible for the inefficient support and breakdown of the foot. Where such an evil arrangement was combined with a flat heel, the shoe is of the worst description. The majority of people habitually wore shoes too narrow across the toes and the balls of the toes. Up to a point, just behind the balls of the toes, the snugger and narrower the shoe the better, for a good tight grip of the instep was very desirable.

In selecting shoes important points to be borne in mind were length, breadth of soles, the pointing inwards of the toe portion or straight inner border, and the roominess of the toe portion of the upper. In conclusion, Mr. Trethowan pointed out that pressure effects began very early in children, and that a single pair of ill-fitting shoes might be the cause of a considerable degree of permanent deformity. Socks and stockings were of some importance also, and were often too short, narrow, and made of unyielding materials. Socks, in order not to have any deforming effects, should be large, not pointed at the toes, and made of material that will readily expand.

ON

LOOSE BODIES IN JOINTS.

A STUDY OF LOOSE BODIES COMPOSED OF CARTILAGE, OR OF CARTILAGE AND BONE, OCCURRING IN JOINTS. WITH SPECIAL REFERENCE TO THEIR PATHOLOGY AND ÆTIOLOGY.[1]

Delivered before the Royal College of Surgeons of England on Feb. 11th, 1921,

BY A. G. TIMBRELL FISHER, M.C., F.R.C.S. ENG.,

ASSISTANT IN THE ORTHOPÆDIC DEPARTMENT, ST. BARTHOLOMEW'S HOSPITAL; SURGICAL SPECIALIST AND ADVISORY SURGEON FOR JOINT CASES, APPEAL BOARDS, MINISTRY OF PENSIONS.

I.—INTRODUCTORY.

THE subject of loose bodies in joints is not only of considerable practical importance, but in addition it constitutes a pathological problem of very great interest, the solution of which has taxed the ingenuity of surgeons and pathologists from the time of Ambroise Paré until the present day. It is scarcely surprising, therefore, that the literature upon the subject is great, and the nomenclature diverse. Unfortunately, the subject of loose bodies in joints, like that of internal derangement of the knee, in spite of the progress that has been made in recent years, is still surrounded by a cloud of mystery and imagination which not infrequently brings discredit upon our profession, and under cover of which the charlatan and "bone-setter" pursue their dangerous and unscientific methods. This cloud can only be dissipated by knowledge of underlying pathological principles. The present article does not discuss the group of loose bodies comprising those formed of unorganised fibrin, fibrous tissue, fat, &c., but confines itself to those bodies formed of cartilage, or of cartilage and bone combined, occurring in joints. Foreign bodies in joints also form a class by themselves and do not come within the scope of this paper.

II.—PATHOLOGY AND SYMPTOMATOLOGY.

The loose bodies of cartilage, or of cartilage and bone, under consideration may be classified into three groups.

GROUP I.—Loose bodies occurring in connexion with some more or less general pathological process affecting the joint, such as: (*a*) osteo-arthritis; (*b*) tabes; (*c*) tuberculous disease accompanied by necrotic caries; (*d*) acute arthritis due to infection.

GROUP II.—Loose bodies occurring in joints that are otherwise apparently normal: (*a*) bodies having the microscopic, and frequently the macroscopic, appearances of detached portions of the articular surfaces; (*b*) bodies derived from inter-articular fibrocartilages; (*c*) bodies formed from detached epiphyses not forming portions of an articulating area.

GROUP III.—Synovial chondromata, laminated and non-laminated: (*a*) single; (*b*) multiple; (*c*) diffuse.

GROUP I.—*Loose Bodies Occurring with Some General Pathological Process Affecting the Joint.*

A. *Loose bodies occurring in osteo-arthritis.*—(1) Synovial chondromata; (2) detached osteophytes; (3) detached epiarticular ecchondroses.

1. *Synovial chondromata in osteo-arthritis.*—These will be dealt with below under Group III., as they present the same naked-eye and microscopic appearances as the synovial chondromata that occur unassociated with osteo-arthritis. They cannot be said, therefore, to be the typical osteo-arthritic loose body, which distinction belongs to the detached osteophyte to be dealt with below.

2. *Loose bodies formed by detached osteophytes.*—It is to John Hunter that we owe the first description of this mode of origin of loose bodies. Bodies of this category have certain definite features which differentiate them from the other varieties, and by which they may at times be readily recognised. They are peculiarly exposed to injury in certain situations, and it is not surprising, therefore, that they may become detached, either completely or incompletely, and in the latter case are often found attached by pedicles of varied thickness to the joint margins. When completely detached the fractured surface of the chrondro-osteophyte may be recognised, but later this may become covered by outgrowth from the surrounding cartilage. In section these bodies are usually somewhat pyriform. The more pointed extremity is less thickly covered with cartilage than elsewhere, and may be regarded as the spot where the osteophyte was attached to the parent bone, the fractured surfaces having become covered with cartilage of new formation.

Microscopical examination of a chondro-osteophyte shows features of great interest, which clearly differentiate this variety from the two other types to be described later, with which it is liable to be confused—i.e., the synovial chondroma and the "classical" type of loose body derived from the articular surface. A section through the entire body shows that the periphery consists of well-developed fibrocartilage with comparatively few, but uniformly distributed, cells. The latter differ from those of connective tissue in that the nuclei are spherical, although they are as yet unsurrounded with capsules. This fibrocartilage is invested with a zone of fibrous tissue furnished with flattened cells as in a perichondrium. In this fibrocartilage occur areas of hyaline cartilage. The bone in the centre consists of well-developed *cancellous tissue, but is quite dead.* The lacunæ are empty, and devoid of any stained elements. The contents of the spaces are mostly groups of fat cells, but there are no stained nuclei either in the fat cells or other tissues. At the junction of the osseous centre and the surrounding cartilage there is, in places, a zone of calcified cartilage between the fibrocartilage and the proper dead cancellous bone, the cartilage cells *in this* zone being alive, but the bone corpuscles dead. The overlying cartilage has nowhere the characters of normal articular cartilage, and there are no proper elongated or other groups at the free aspect.

To sum up: A detached osteophyte forming a loose body in a joint has definite naked-eye and microscopic appearances by which it may be recognised. *It is very unusual* for more than two or three of these bodies to be found in the same joint, and there is often only one of this variety present. In the same joint, however, there may co-exist cartilaginous loose bodies derived from synovial fringes.

3. *Detached epiarticular ecchondroses.*—Professor S. G. Shattock was the first to point out that bodies of the same essential nature as the periarticular ecchondroses growing from the articular margins might arise in the substance of the cartilage covering the normal bone. This takes place by local hyperplasia of the cartilage, in which central ossification subsequently occurs (Path. Trans. xl.).

These observations suggest (as Professor Shattock observes) that in certain cases the separation of such might lead to the production of loose bodies of a kind similar to those which are at times detached from the articular margins.

B. *Loose bodies occurring in tabes.*—These resemble the bodies described in the last group, but all the processes tend to become greatly exaggerated, so that the loose bodies, whether formed from synovial fringes or by detachment of osteophytes, are as a rule larger. In tabetic joints, especially in the "hypertrophic" form, the osteophytes may be indeed enormous; moreover, the formation of bone involves the planes of connective tissue between the capsule and the synovial membrane, *so that the joint may be surrounded eventually by bony* masses, sometimes accurately articulated.

C. *Loose bodies occurring in tuberculous disease accompanied by necrotic caries.*—Tuberculous necrosis of considerable portions of bone is not a common condition. It affects more frequently the articular end of the femur, and is probably due to interference with the blood-supply of the affected portion, which may account for the wedge-shaped or conoidal form of these sequestra. A remarkable feature is the slowness of the process by which their separation is accomplished.

D. *Loose bodies occurring in acute arthritis due to infection.*—These occur in the following forms: (1) Flakes of necrotic articular cartilage of variable size; (2) bony sequestra; (3) the whole of the articular end, when the epiphysis is intracapsular, may necrose and be found quite loose in the joint. (Fig. 1.)

GROUP II.—*Loose Bodies formed by Detachment of a Portion of the Articular Surface and occurring in otherwise Normal Joints.*

General Characteristics.

1. They occur more frequently in males than in
2. The commonest age-incidence is between the years 15 and 25.
3. The type of loose body most frequently seen I termed the "classical" form. This form has the follo

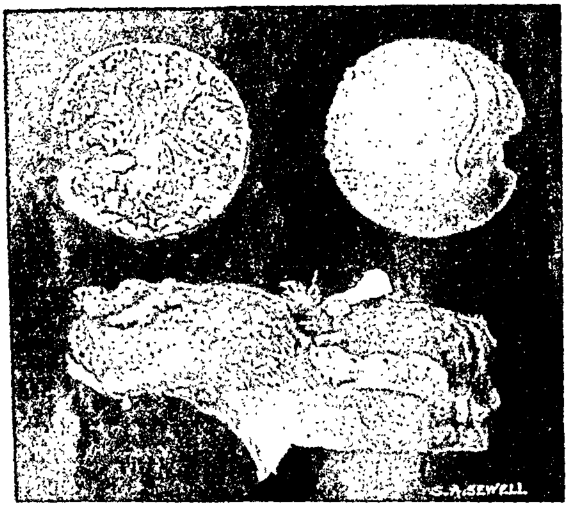
No. 509

R

characteristics:—Shape, circular or oval; size, that of an almond; section, plano-convex. Surfaces: The convex surface has the typical appearance of articular cartilage, whereas the flattened surface is more irregular and may be rough, lowly nodulated, or smooth, according to the degree of proliferation that has taken place. The borders are smoothly rounded.

4. Their commonest site is the knee, next in frequency the elbow. Their presence has been recorded, although rarely, in the shoulder, hip, ankle, wrist, and other joints. In the case of the knee-joint they are usually derived from the articular surface of the femur or patella, and but rarely from that of the tibia.

FIG. 1.



Head of femur forming loose body in acute infective arthritis Natural size. [721 A, St. Thomas's Museum.]

5. Although usually single, occasionally two or even three of these bodies may be present in a joint.

6. The bodies may be completely or incompletely detached or may acquire a secondary adhesion to the synovial membrane. When incompletely separated they are usually attached by a hinge of articular cartilage to the margin of a defect or loss of substance in the articular surface which corresponds in size and shape to the loose body. In cases where more than one body is present, these may be quite free, or one may be incompletely detached and the remainder free.

7. Cases are recorded where such a gross detachment by injury as the head of the femur or of the radius may occur and form a loose body in the joint.

8. Their continued presence in a joint may bring about secondary changes of an osteo-arthritic nature.

9. These loose bodies themselves undergo certain remarkable changes in the joint which will be dealt with in detail below.

10. The part that trauma plays in their ætiology has been a subject of great controversy, and we will defer our conclusions upon that question until we have critically examined the series of cases to be next described.

11. They are occasionally bilateral and symmetrical (Bowlby, Clutton, Weichselbaum).

A. Loose bodies having the appearances of detached portions of the articular surfaces.—Classification: I have adopted the following subdivisions: (1) Recent detachments. Bone (where present) and articular cartilage living. No proliferative charges in articular cartilage. (2) Bodies whose sojourn in the joint has been longer. The articular cartilage shows proliferative changes. The "classical" type of loose body. (3) Marked degree of proliferation of cartilage. (4) Excessive proliferation of cartilage. (5) Feeble proliferation of cartilage. (6) Formation of new bone from the osteogenetic tissue in the cancellous spaces accompanying the formation of secondary adhesions, or incomplete detachment.

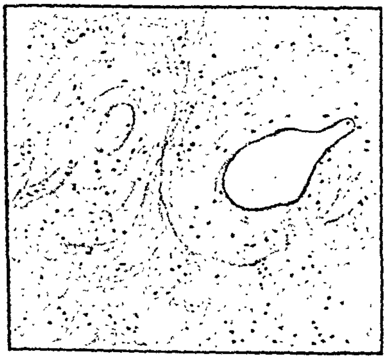
A series of cases illustrating recent detachments was then passed under review.

1. *Recent detachments.*—In this series a portion of articular cartilage, with or without a layer of the subjacent bone, is detached by direct or indirect violence. The following cases are typical examples representing four different varieties: Cases 1 and 2, detachment of articular cartilage and bone by direct violence; Case 3, detachment of articular cartilage and bone by indirect violence; Case 4, detachment of articular cartilage by direct violence; Case 5, detachment of articular cartilage by indirect violence.

2. *Loose bodies in which the cartilage shows proliferative changes. The "classical" type of loose body.*—In this subdivision a few cases only out of the large number examined will be passed under review. Although they are all alike in showing proliferation of cartilage, they present certain minor differences. The principal naked-eye features of this subdivision have been already described. It will be sufficient merely to draw attention again to the fact that the margins of the bodies comprising this group, instead of showing signs of recent traumatic detachment, are smooth and rounded. Many different theories have been held as to their origin, but I shall attempt to show that they are portions of the articular surface detached by trauma and not by any pathological process, and which have continued to grow until, as we shall see later, their origin may be obscured.

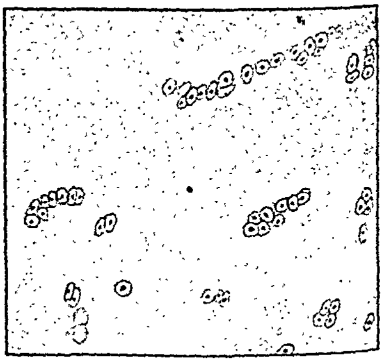
CASE 1.—E. J. D., 25, came under my care in November, 1919, with the following history. Before the war he had been a miner; he had never had any illness that he could remember, and had never had any joint trouble. In January, 1915, he joined the Royal Field Artillery, and almost immediately commenced to undergo the strenuous riding-school exercises. After a short time he noticed that his knee would occasionally become painful and swollen after riding. The pain and swelling recurred at intervals after strenuous exercise for about two and a half years. In August, 1917, his knee suddenly became fixed in the extended position as he was getting up to leave a train, and rapidly swelled. He was admitted to hospital with the knee locked in extension. He was treated for some months as a case of "arthritis," and the limb was immobilised by splints. The treatment caused the swelling to subside, but whenever he attempted to walk the pain and swelling recurred, and the limb was immobilised once more. After a long period of immobilisation the tendency for pain and swelling to occur after exercise subsided, and he was ordered a course of gymnastic exercises to remove stiffness that was present, and he was so far improved that he was able to return to duty in February, 1918, and returned to France again the following month. The result was disastrous; the pain and swelling constantly recurred, and at length, in December, he was discharged the Service permanently unfit. After discharge his symptoms continued, but in addition, he became subject to attacks of severe pain in the joint which caused him to fall to the ground. In November, 1919, he was going up some steps when his left knee suddenly "twisted inwards" and became locked in a semiflexed position, so that he was unable to straighten it.

FIG. 2.



Living bone corpuscles. [722 St. Bart.'s.]

FIG. 3.

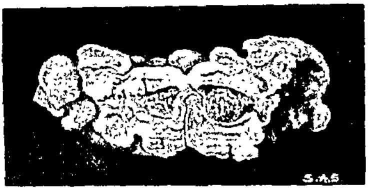


Living cartilage cells. [722 St. Bart.'s.]

When I saw him there was a considerable amount of effusion in the joint, and any attempt to extend the leg upon the thigh caused severe pain, more marked beneath the patellar ligament. At first sight this appeared to be a case of internal derangement of the knee due to injury and displacement of the internal semilunar cartilage. However, as all attempts to unlock the joint were unsuccessful, the patient was X rayed and a loose body revealed. At operation I found the loose body lying in the depression of the articular surface of the external condyle of the tibia between the external semilunar cartilage and the tibial spine. It was easy to see how its position mechanically blocked full extension of the leg. It was attached by a pedicle to the posterior crucial ligament in the region of the intercondylar notch. After division of the pedicle the loose body was removed, and the patient made an uninterrupted recovery.

From a consideration of the history it appears probable that during the riding exercises a portion of articular cartilage was gradually detached, probably by ligamentous strain or muscular spasm, and that eventually it became completely detached and caused the first locking of the joint. Afterwards the body perhaps acquired a secondary attachment to the synovial membrane over the crucial ligament, which, on stretching, gave rise to the second period of locking. Incidentally the history shows the difficulties and pitfalls that lie in the path of the clinician in these cases. The patient's condition remained undiagnosed for nearly four years; he suffered much pain and discomfort, and was eventually discharged "permanently unfit." An exploratory arthrotomy might have at once revealed the condition, spared him years of suffering, and supplied another soldier for the firing line.

FIG. 4.



Loose body derived from articular surface showing striking degree of proliferation. Natural size. [1931 B, R.C.S.]

Microscopical appearances.—A portion cut from the dried specimen after immersion in water regained its normal appearance; and microscopic sections, after staining with hæmatoxylin, displayed well-stained cartilage cells throughout—i.e., it is *not a sequestrum*.

I am indebted to Mr. Percy Sargent for loan of the following specimen.

CASE 2.—W. G., aged 20, came under Mr. Percy Sargent's care in May, 1920, with the history that nine months ago he "ricked" his right knee whilst swimming, and experienced severe pain in the outer side of the joint, and almost immediately after noticed a freely movable body in this situation. No locking occurred, but movements were painful. Afterwards the knee was apt to give way suddenly about once a fortnight, with excruciating pain—the loose body on these occasions being felt as before at the outer side of the joint. There was never any actual locking.

On admission the knee was slightly swollen and the synovial membrane thickened. Movements of the joint were full, and no loose body could be felt. There was some wasting of the thigh. Mr. Sargent obtained access to the joint by the vertical median division of the patella. The body lay quite loose behind the patella.

The loose body has the characteristics of the "classical" type already mentioned. The rounded bodies are well seen, and the deep surface shows that the articular cartilage has extended from the margin of the body over the surface of the bone. This process is more advanced than in Case 1.

Microscopical appearances.—From the fractured edge of the original large-celled articular cartilage a cushion of small-celled cartilage has been produced, which extends over the edge and over the under side of the fractured bone. The bone itself is necrosed, the corpuscles in the trabeculæ ceasing to take a nuclear stain. The connective tissue within the cancellous spaces is quite dead; the forms of the fat cells in the cancellous spaces, however, being still recognisable.

At the top of the specimen is seen the free surface of the reparative tissue or "callus;" which has spread from the proliferating fractured edge of the articular layer, over the opposite aspect of the fractured surface of the bone, as indicated by the fissure between the two.

The reparative tissue is well developed on the deep aspect, the cartilage cells being furnished with well-pronounced capsules. One process has intruded itself into one of the cancellous spaces laid open by the fracture. At the lower right-hand side another elongated cancellous space is completely filled with a deeper intrusion of cartilage, the matrix of which is coloured a vivid blue; there were several adjacent spaces occupied with similar newly formed cartilage. The lacunæ of the osseous trabeculæ are quite empty, the bone itself being dead.

[Professor Fisher next described the microscopical appearances in a number of other cases somewhat similar to the last but presenting minor differences.

In Case 6 (Spec. No. 722, St. Bart.'s Museum: Figs. 2 and 3), although in the absence of any history of injury it had previously been inferred that the body had become detached through "quiet necrosis," yet microscopic examination shows that the cartilage cells and bone corpuscles are all living.]

3. *Loose bodies exhibiting a striking degree of proliferation.*—The phenomena presented by this subdivision are truly remarkable; the cartilage cells proliferate with such exuberance that veritable cartilaginous tumours are formed. In the centre of the body can be seen the fragment of the articular surface originally detached.

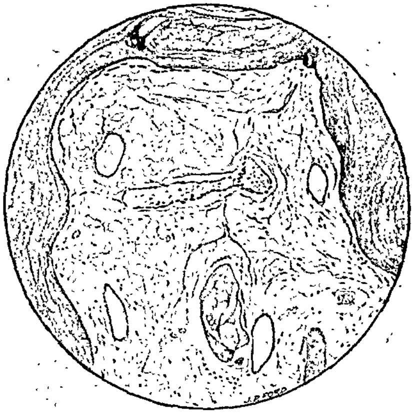
CASE 1.—Consists of two loose bodies of unusually large type which were removed from a knee-joint. They are both somewhat discoidal in form, and have a remarkably irregular, coral-like exterior, like some of the osteomata growing from the ends of the long bones; the larger has a chief diameter of 2¼in. The smaller of the two bodies has in the centre a nucleus of dense osseous tissue which is covered on one aspect by a layer of cartilage having the appearance of articular cartilage. Next succeeds a thick crust of cartilage which is obviously laminated in a circumferential manner. This external crust is traversed in places by fissures which have for the most part a radial arrangement. The accompanying description states: "They were removed from the knee-joint of a labourer, aged 25. The loose bodies lay in the cul-de-sac beneath the quadriceps extensors, and were very freely movable. The patient noticed a swelling in that situation after a fall on the knee five years previously. The margins of the femur were lipped but there was no other evidence of osteo-arthritis."

CASE 2 (Spec. 1931B, Museum, R.C.S., Fig. 4), is an equally remarkable example of very marked degree of proliferation of the articular cartilage. The short accompanying description states that: "It was removed by operation from the knee-joint of a man, aged 55, who had been unable to flex his leg to the full extent for some months. A hard movable body could be felt in the suprapatellar recess of the joint previous to operation. There were evidences of rheumatoid arthritis in the knee."

4. *Feeble proliferation of articular cartilage.*—This is a rare condition, and is represented by but one example among the large number examined in the course of this research. This specimen, kindly lent me by Professor M. J. Stewart, of Leeds, is the one described by Teale, who considered that it had been gradually exfoliated after injury.

Microscopical examination. The cartilage cells towards the free surface stain feebly (possibly the result of imperfect fixation). More deeply the groups of cells and their nuclei are sharp and the nuclei fairly, not intensely stained. On the free deep side here and there are portions of large-celled cartilage.

FIG. 5.



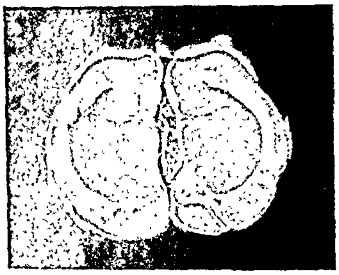
Formation of new bone in cancellous spaces of a loose body accompanying secondary adhesion to synovial membrane.

5. *Formation of new bone from osteogenetic tissue in cancellous spaces accompanying the formation of secondary adhesions or incomplete detachment* (Fig. 5).—In the cases hitherto described it is to be noticed that no case demonstrates new bone in process of formation. The cancellous spaces contain merely necrotic tissues, and no living and active osteogenetic cells. It will have been noted that these bodies were all quite free in the joint. The examples of the subdivision we have now to consider were found at operation to have acquired a secondary adhesion to the synovial membrane or to be incompletely detached. In this variety we find that the cancellous spaces still contain living contents and vessels, and that although many of the deeper bone corpuscles—that is, those lying nearer to the articular cartilage—are dead, yet the more superficial cancellous

spaces contain osteogenetic tissue actively engaged in laying down new bone upon the surface of the old. There can thus be little doubt that a loose body may, if attached secondarily to the synovial membrane or if incompletely detached, increase in size, not only by proliferation of its cartilage cells, but also by formation of new bone. Moreover, it appears that, should secondary detachment of the loose body occur, the formation of bone ceases, whereas the cartilage continues its growth. This increase in bony substance of an attached loose body is important from the ætiological point of view, as we shall see later, particularly in those cases where a loose body attached to the crucial ligament of the knee-joint occupies a pit on one or other femoral condyle. At first sight it would appear difficult to understand how such a body could be detached by traction of the ligament, unless we realise that the bone has probably continued its growth after incomplete detachment.

B. *Loose bodies derived from interarticular fibro-cartilages.*—The subject of injuries to the semilunar cartilages of the knee-joint is a large one, and is beyond the scope of the present article; I am, moreover, making it the subject of a further research. It will suffice to mention here that a portion of one of the semilunar cartilages—usually the anterior end of the internal semilunar—may occur as a rounded cartilaginous body, either attached by a pedicle of variable thickness to the remainder of the cartilage, or the pedicle may rupture and the body become quite free.

FIG. 6.



Epiphysis of ext. condyle of humerus forming loose body in elbow-joint. Natural size. [714 C, St. Bart.'s.]

I have seen the internal semilunar cartilage completely detached from its site and with a secondary attachment round the periphery of the patella. Occasionally the posterior horn of one of the semilunars may form a pedunculated loose body in the joint.

C. *Loose bodies formed by detached epiphyses not forming portions of an articulating area.*—(Spec. 714C St. Bart.'s Hospital, Fig. 6.) This loose body was removed by Sir Charles Gordon Watson from the elbow-joint of a boy, age 17, in whose joint it had been present for four years. There can be little doubt that the body is a detachment of the epiphysis of the external condyle of the humerus. One surface of the loose body is convex and lowly nodulated, the other surface being concave. The section shows that there is a nucleus of bone in the centre, and that the convex aspect is covered by a thick layer of cartilage, which has also apparently spread over the concave detached surface. This cartilage has none of the characteristics of articular cartilage.

GROUP III.—*Synovial Chondromata, Laminated and Non-Laminated.*

They may be divided into three classes: (*a*) Single (Fig. 7), pedunculated or free; (*b*) Multiple, pedunculated, free, or the two conditions combined; and (*c*) Diffuse (Fig. 8), usually associated with free bodies in the joint cavity. The discovery by Kölliker of cartilage cells in the villi of the synovial membrane and the observations of Rainey have already been referred to in Section I. The loose bodies of the important group we are about to pass under review, although they may differ in structure and form, have the common characteristic that they have originated from the cartilage cells of the synovial villi, and are, therefore, true chondromata. It is impossible in the present state of our knowledge to assign a cause for this behaviour of the cartilage cells. In many cases there is a history of injury; in others this is absent, and they often appear to occur in the course of chronic synovitis. Whether, however, the presence of the synovial chondromata caused the synovitis, or the latter was the exciting cause of the tumour formation, it is impossible in many instances to say.

[Professor Fisher then described the naked-eye and microscopical features of the three classes of synovial chondromata.]

III.—ÆTIOLOGY AND PATHOLOGICAL DEDUCTIONS.

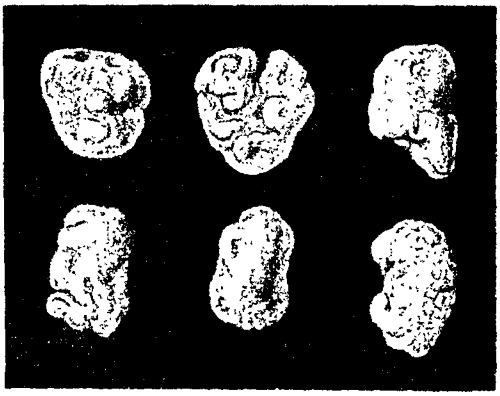
In the present stage of our knowledge it is impossible to dogmatise upon the ætiology of the more important loose bodies of Group I.—i.e., the osteophytes, since it is bound up with the larger question of the ætiology of osteo-arthritis. Similarly, the ætiology of Group III., the synovial chondromata, is bound up with the larger question of the ætiology of tumours. Although it is probable that the cartilage cells in the synovial villi from which they originate are, as Professor Shattock pointed out, derived from the primitive cartilaginous bar which in the developing embryo becomes cleft to form the knee-joint, the periphery remains to become the capsule and synovial membrane. Trauma, however, may undoubtedly be a contributory factor. In one of my cases the patient was struck a severe blow just above the patella a year previous to the X ray examination, which revealed multiple synovial chondromata developing in the suprapatellar joint recess. This section will therefore deal principally with the ætiology of the type of loose body derived from the articular surface (Group II., Class I.).

A.—*Deductions from the Pathological Data.*

1. When composed of articular cartilage only the later, so *far from being necrosed*, is *perfectly healthy* (except, perhaps, in the Teale case) and in many cases actually proliferates. Anything more unlike a sequestrum in its behaviour it would be impossible to imagine.

2. In the large series examined there were no signs of any pathological process, such as pitting due to phagocytic action such as a sequestrum shows, and no layer of granulation tissue or fibrous tissue on the deep surface. On the other hand, the deep surface had in many cases all the appearances of a fractured surface. The series examined has included many of the specimens from pathological museums labelled "*quiet necrosis.*"

FIG. 7.



Multiple chondromata of synovial membrane. Natural size. 720 B, St. Bart.'s.]

3. In those cases where it has been possible to ascertain whence they have arisen, they are found to arise from those parts of the joint surfaces most exposed to injury.

4. They often present to the naked eye the form of grooves on the articular surface associated with fracture of the subjacent bone of traumatic origin.

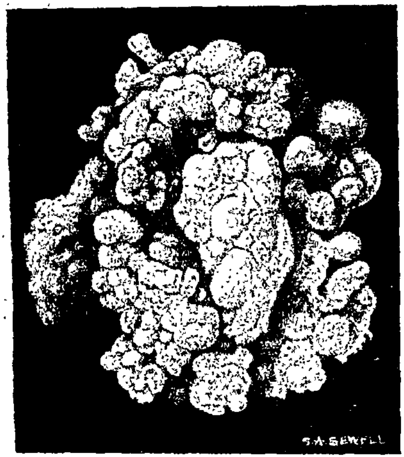
5. Although many of the bone corpuscles are dead in cases where the loose body consists of bone in addition to cartilage, yet it is clear that their death has taken place *after* and not before detachment, and this fact cannot therefore be adduced in favour of some pathological process such as "quiet necrosis." In the experiments to be described below, identical appearances are seen, and here there can be no question that the death of the bone corpuscles must have taken place *after* detachment of the loose body. We see exactly the same behaviour of the bone corpuscles in experimental bone grafting, for Hey Groves, Axhausen, and others have shown that the majority of the bone corpuscles in a bone graft die. We shall refer to *this* again later under conclusions. Moreover, as previously mentioned, in the only case in the whole series where there was no history of injury, and where we should expect to see marked evidence of some pathological process, such as "quiet necrosis," we find that the bone corpuscles are all living.

To sum up the pathological data, the naked-eye and microscopical features of this group of loose bodies demonstrate that they are detached by trauma.

B. *Deductions from the Clinical Data.*

1. *Traumatic factor.*—Martens, who made an analysis of König's cases, found that out of a series of 54 cases there were 20 with a definite history of antecedent trauma, and 34 where this was absent or of an insignificant nature. But, as we have shown above, all figures not based upon microscopic examination of every case are fallacious, owing to the way in which the solitary osteo-arthritic loose body may simulate the traumatic type. In my own series of cases quoted above, all of which were examined microscopically, there were 16 cases; of these, 3 cases had no accompanying history, and may be discarded for statistical purposes, leaving 13 with an accompanying history. In 12 out of the 13 there was a definite history of antecedent trauma, 6 being cases of direct and 6 of indirect injury. In only 1 case was there no history of antecedent injury, yet in this case not only the cartilage cells but all the bone corpuscles were perfectly healthy, and there was no sign whatsoever of any morbid process. The clinical evidence from this source strongly supports, therefore, the traumatic origin of this group. Further to investigate this point I searched through the surgical records of St. Bartholomew's Hospital, and found that in the last 17 years there have been 20 cases of solitary loose body operated upon. These were not all examined microscopically, and therefore almost certainly include a certain number of the solitary pathological variety, yet in no less than 80 per cent. of these cases was there a definite history present. If we were able to exclude the pathological type in this series it is obvious that the percentage would be still greater. Surely it is reasonable to assume that in the small percentage of cases remaining, in which no history of injury is present, leading questions were asked as to a direct injury and the possibility of indirect was overlooked or forgotten.

FIG. 8.



Diffuse chondroma of synovial membrane. Natural size. [720 C, St. Bart.'s.]

But it may be asked, How can indirect injury lead to a detachment of a portion of the articular surface? I believe that in many cases they are pulled off by the crucial ligaments, and it is certainly remarkable that these bodies are commonly derived from the area near the attachment of one or other crucial ligament. In the knee-joint of a full-term fœtus, by fully flexing the knee and then internally rotating, a very large piece of the inner portion of the external condyle of the femur can be wrenched off. Then another and, I believe, not infrequent detachment by indirect injury is produced by violent tension upon the posterior ligament of the knee-joint, which, it will be remembered, is attached immediately adjacent to the articular margin and is powerfully reinforced by the tendons of the gastrocnemius and semimembranosus muscles.

Sir Anthony Bowlby has drawn attention to a specimen in St. Bartholomew's Museum consisting of two portions of cartilage which were removed by operation from the knee-joints of a boy, age 18, by Holden, and each exactly resembles the cartilage over the posterior aspect of the condyles. There was a year's interval between the two operations.

2. *Interval occasionally occurring between injury and onset of classical symptoms of a loose body.*—Supporters of the theories of "quiet necrosis" or "osteochondritis dissecans" lay considerable stress upon this interval. Yet the interval can be satisfactorily explained if we bear in mind that the classical symptoms are due to the loose body being caught between the articular surfaces, this giving rise to sudden attacks of pain or even locking. If the loose body has become attached to the synovial membrane in such a position that it is unable to wander freely about the joint or get between the articular surfaces, or if it has not been completely detached and occupies a pit in the articular surface, then the classical symptoms may not arise. Should it eventually become completely free more definite symptoms may arise.

The clinical evidence would therefore appear to favour strongly the traumatic origin of loose bodies of the "classical" type.

C.—*Deductions from Experimental Observations.*

1. *Experiments upon the cadaver.*—Although it is scarcely logical to argue from the dead to the living, yet I have been able, exercising quite moderate violence, to detach, both completely and incompletely, portions of the articular surface of the femoral condyles in the cadaver. I found that a blow by a hammer upon the lateral margin of the condyle produced a detachment of a portion of articular cartilage, this detachment usually occurring through the brittle calcified zone. If, however, the surface of the condyle was struck, a much greater degree of violence was necessary to detach a portion of the articular surface. I have already referred to my artificial production of loose bodies by tension upon the crucial ligaments.

2. *Experiments upon animals.*—These yield results of great interest. I describe here a typical experiment upon the knee-joint of a rabbit, where a small portion of the articular end of the femur was detached by a chisel after opening the joint, the artificially produced loose body being subsequently examined. First operation: The right knee-joint of a rabbit was opened from the inner side. A small portion of articular cartilage with a portion of the subjacent bone was chiselled off—the portion involving the inner lip of the trochlear surface of the femur and a small portion of the inner condyle of the femur. The portion was completely detached and pushed up into the suprapatellar recess of the joint. The joint was then closed, the incisions in the capsule and skin being separately sutured with catgut and a collodion dressing applied. Second operation: The joint was reopened five weeks later, and the loose body found to have acquired a secondary attachment to the synovial membrane of the suprapatellar pouch. This attachment was divided with scissors and the loose body removed.

Microscopical examination revealed general features resembling a loose body of the classical type in that the majority of the cartilage cells are perfectly healthy but many of the bone corpuscles are dead. But the latter must have died *after* detachment; therefore it seems reasonable to assume that the bone corpuscles in the classical type of loose body have also died after the detachment by trauma, and that their death is not due to any morbid pathological process. The experimental data, in addition to the pathological and clinical data, are thus consistent with the traumatic origin of the classical type of loose body occurring in joints.

Deductions upon Cartilage Vitality Growth and Repair to be Drawn from a Study of the Pathological Data.

A. *Vitality of articular cartilage.*—The first fact of interest to be noted is that the behaviour of the cartilage cells demonstrates that their vitality has been considerably underestimated. A loose body of the traumatic type when free in a joint is essentially an autoplastic graft surrounded by the synovial fluid, and when the loose body is composed of both cartilage and bone we have an excellent opportunity of observing and comparing the behaviour of these two substances. One then observes that the cartilage cells retain their vitality in almost every case and after a time actively proliferate, but that the majority of the bone corpuscles die, as do also the contents of the bony spaces. As we have mentioned previously, we see the same difference in behaviour between cartilage cells and bone corpuscles after transplantation of joint ends.

B. *Growth and repair of articular cartilage.*—Present-day teaching is largely based upon the experiments of P. Redfern, performed in pre-antiseptic days. The general conclusions drawn from these experiments was that cartilage cells were destitute of the powers of repair. Yet there can be no doubt that the phenomena described above refute the conclusions arrived at by the earlier experiments. At present I am performing a series of experiments upon animals in order further to investigate growth and repair in cartilage, and which will be made the subject of a further communication.

C. Growth and repair of cartilage other than articular.—Professor Shattock has kindly allowed me to reproduce in this connexion one of his hitherto unpublished observations, showing the reparative production of new cartilage from the cut edges of one of the tracheal rings which was divided six years previously in a tracheotomy. The opposite edge of the cut surface of the same ring showed precisely the same repair. The actual interval between the two is filled with dense fibrous tissue. The specimen was obtained from a boy, aged 15, upon whom tracheotomy had been performed six years previously. This specimen shows with almost startling clearness that cartilage cells are capable of growth and repair.

Application of these facts to cartilage-grafting.—Owing to the inherent vitality of cartilage cells it is clear that the use of cartilaginous grafts in surgery is based upon sound principles. Morestin has done excellent work in this connexion, and has used autogenous grafts of costal cartilage to repair defects in the cranial wall and facial skeleton.

Deductions to be Drawn from a Study of the "Classical" Type of Loose Body upon the Behaviour of the Bone Corpuscles in an Autogenous Graft.

From a study of the pathological appearances in the cases that we have described of loose bodies of bone and cartilage quite free in the joint, it is clear that, except in one case, the majority of the bone corpuscles were dead, as exemplified by the lacunæ no longer holding stainable cells, and by the fact that the spaces contain nothing that stained and were, in fact, empty. Furthermore, in not a single case was there any evidence of proliferation of osteoblasts with formation of new bone. Yet we see a striking difference on examining those bodies of traumatic origin and containing bone which have acquired an early adhesion to the synovial membrane. For in these cases fresh capillaries can be seen to have penetrated the cancellous spaces, and active proliferation of osteoblasts with formation of new bone is taking place. Exactly the same thing can be observed in the experimental production of loose bodies which show secondary attachment to the synovial membrane with active proliferation of bone cells.

These observations therefore support Hey Groves's contention that the osteogenic cells in the Haversian canals and cancellous spaces of an autogenous bone-graft actively proliferate only if the graft becomes to some extent vascularised by the ingrowth of capillaries from surrounding parts. As, therefore, the vascular supply appears to be of such paramount importance in the osteogenetic function of the bone-graft it would appear to be advantageous to retain the periosteum in order to enable the graft to establish its vascular connexions as rapidly as possible. And in grafting cartilage the indication would appear to be to retain the perichondrium in order to supply an additional aid to any further production of the cartilage.

IV.—DIAGNOSIS AND TREATMENT.

Diagnosis of the traumatic loose bodies.—Considerations of space will not permit the enumeration of a number of case histories, and compels me to summarise my conclusions from these. If we bear in mind the pathological and experimental data it will help us to understand the often extremely puzzling symptoms to which a loose body may give rise. We have seen that a portion of the articular surface may in the first place be incompletely detached, in which case it may lie snugly in place, flush with the articular surface; or, on the other hand, it may be capable of considerable movement. Secondly, the detached portion may be quite free in the joint. Thirdly, it may acquire a secondary adhesion to the synovial membrane.

Now the classical symptoms of a loose body, which are sudden attacks of severe pain, often followed by swelling or momentary locking, are due either to the body becoming suddenly and momentarily nipped between the articular surfaces or between the capsule and the joint ends. These symptoms cannot arise when either the body is firmly attached to the synovial membrane at some point where it cannot get between the articular surfaces or when it is incompletely detached and lies snugly in situ. Bearing these facts in mind, it is possible to describe three different groups into which the symptoms fall and place side by side with the symptoms the corresponding pathological picture.

Group 1.—A portion of articular surface is completely detached; wanders freely about joint; and after an interval becomes secondarily attached to synovial membrane. An injury, direct or indirect, is followed almost immediately by classical symptoms; and after an interval these disappear.

Group 2.—The portion of articular surface is completely detached, becomes almost immediately adherent to synovial membrane; but after an interval it becomes detached therefrom. An injury, direct or indirect, is followed by freedom from classical symptoms; but after an interval the latter symptoms arise.

Group 3.—A portion of the articular surface is *gradually* detached; at length it becomes freely movable or completely detached. Here the process of gradual detachment is accompanied by attacks of pain and swelling, often increasing in severity, and these are followed at last by the classical symptoms. These again may disappear when the body becomes secondarily attached to the synovial membrane.

Symptomatology of the pathological varieties.—The symptoms to which the solitary osteo-arthritic body or the solitary synovial chondroma may give rise are almost identical with those we have already described. When, however, multiple synovial chondromata are present, we find that, as a rule, owing to their number and smaller size, the bodies are apt to become caught between the joint surfaces much more frequently. This occurrence is, however, not associated with such pain or inconvenience to the patient as in the case of the solitary varieties.

Treatment.—The treatment in the case of the traumatic loose bodies and of the synovial chondromata is, in most cases, removal. In the former group, provided the aseptic technique is beyond reproach, the results are naturally good, since they usually occur in a joint that is otherwise normal. However, if the traumatic loose body has been allowed to remain in the joint long enough to cause a chronic villous synovitis or commencing osteo-arthritis, although we may cure the sudden attacks of pain due to the body becoming impinged between the articular surfaces, yet the operation may be followed by pain, swelling, and feeling of weakness in the joint due to the superimposed condition. This forms one argument for early operation, another being that the presence in a joint of a loose body is a source of danger, as when a loose body suddenly becomes impinged between the articular surfaces of the knee when crossing a crowded street. These propensities of loose bodies also interfere with athletic pursuits.

In the case of the pathological loose bodies in osteo-arthritis, an operation is usually indicated in young or middle-aged people when troublesome locking occurs and when the joint is not seriously disorganised. The operation has naturally no effect on the course of the disease, and is of a palliative nature. The results of operation in the synovial chondromata are also good, provided the condition is not progressive, for the process may end as suddenly and mysteriously as it commences. If we are lucky enough to operate when the process has come to an end the result is generally good; if not, further operations may be required. I saw recently a man who, 15 years ago, while in India had over 700 cartilaginous loose bodies removed from his left knee. On examination his knee appeared perfectly normal, and it caused him no trouble whatsoever. Any operation for removal of a loose body or bodies should be preceded by an X ray examination taken in two planes, from which we may learn how and where to open the joint. An X ray is only helpful when the loose body contains bone. In every case incision through the skin and capsule should be liberal, in order to explore the joint as thoroughly as possible. To transfix and remove the loose body through a button-hole incision is an unscientific procedure reminiscent of pre-antiseptic days, for unless we explore the joint we are very apt to overlook other loose bodies or co-existent conditions which may give rise to a recurrence of the symptoms.

It is my pleasant duty to express my indebtedness to Professor S. G. Shattock, who has throughout the research given me much help, advice, and criticism, and has also kindly placed at my disposal the pathological collections at the Royal College of Surgeons and at St. Thomas's Hospital. To the Medical Research Council, under whose auspices the research has been conducted, my thanks are also due. I am also indebted to Dr. T. H. G. Shore, Curator of the Pathological Museum of St. Bartholomew's Hospital for loan of many specimens; to my chief, Mr. R. C. Elmslie, for many helpful suggestions; and to Professor A. Keith for kindly allowing me to work at the Royal College of Surgeons, and for other valuable assistance.

Oliver-Sharpey Lectures

ON THE

NATURE OF FLUTTER AND FIBRILLATION OF THE AURICLE.

Delivered before the Royal College of Physicians of London on April 12th, 1921,

BY THOMAS LEWIS, M.D., F.R.C.P. LOND., F.R.S.,
PHYSICIAN TO THE STAFF OF THE MEDICAL RESEARCH COUNCIL; PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL, LONDON; HONORARY CONSULTING PHYSICIAN TO THE MINISTRY OF PENSIONS.

LECTURE II.—AURICULAR FIBRILLATION.

IN the first of these lectures I have endeavoured to put before you the chief conclusions which we are able to form respecting that rather rare condition, auricular flutter, and have stated that flutter as it occurs in man is due to a single wave circulating continuously. In this lecture I propose to deal with the much commoner, and therefore more important, disorder, auricular fibrillation. Now these two conditions are very closely related, as has been recognised for some years; they are known to be related not only because of several resemblances, but because the one not infrequently passes into the other. Thus flutter of the auricle, as I pointed out some years ago, may usually be converted into fibrillation by the administration of heavy doses of digitalis—a conversion which is made use of in the present-day therapy of flutter. We shall see presently how the two states are related, and that circus movement underlies both. To explain the inter-relation it is necessary for me to expand what I have already touched upon—namely, certain reactions of the auricular muscle to increased rate of beating. We must study in more detail the change which occurs in the length of the refractory period and in the rate at which the waves travel as the rate of beating rises.

INFLUENCE OF HEART-RATE ON THE REFRACTORY PHASE, ETC.

The changes are somewhat complex and may be illustrated most clearly by means of the accompanying diagram (Fig. 1). To the left of the diagram is a double-headed arrow, which represents the length of the auricular cycle when the heart is beating at a normal rate. This cycle is divisible into two parts, as indicated by the two double-headed arrows which stand just to the right of the first; it is divisible into the *refractory period*, during which the auricular muscle is in the excited or contracted state, and into the *responsive period*, during which the muscle is inactive or resting. I represent the refractory period in black and the responsive period in white, and the remainder of the diagram shows, on the basis of direct observation, how these two periods are proportioned to each other as the heart-rate is raised. As the heart-rate rises by equal increments—say from 100 to 150 to 200 to 250, &c. —so the length of the cycle shortens. If the lengths of the cycles, as these shorten, are charted vertically upon a horizontal base line (as in the figure), their ends join up to form a curve, the steepness of which gradually decreases. The curve of the end of the cycle approaches the base line, at first rapidly, but gradually less rapidly. The two lines will meet at infinity. The end of the refractory period also forms a curve which moves towards the base line (it is represented by the top edge of the black portion of the figure). Briefly, the refractory period of the muscle shortens, as does the length of the contraction when the heart-rate is raised. But the refractory period does not shorten to the same extent as does the length of the cycle; consequently, the *responsive period* dwindles when the rate is advanced. It dwindles until eventually and at a very high rate of beating it disappears altogether. When this happens the muscle will not respond to every impulse reaching it; it breaks into what has been termed 2 : 1 (or half) response—that is to say, it responds only to alternate impulses entering it. That is but natural, seeing that only alternate impulses will fall during the responsive period of preceding cycles.

Now the precise manner in which this alternating response is foreshadowed in the mammalian auricle is peculiar and considerably important; it is necessary thoroughly to understand it. As the rate of beating rises and the period of responsiveness shortens a time comes when the muscle develops what is spoken of as a *partially refractory period*. It is a phase of the cycle during which the muscle as a whole *may* or *may not* respond to stimulation. When this partially refractory phase first develops the cycle seems to be divisible into three parts: at the beginning is the absolutely refractory phase; this is succeeded by a partially refractory phase; a short phase remains at the very end of the cycle, during which the muscle is always responsive to stimulation. But the end of the partially refractory phase is not sharply defined; it fades imperceptibly into the phase of responsiveness. If you will, the matter may be expressed somewhat differently. During the early and greater part of the cycle the muscle is quite refractory, but the end of this phase is no longer clean cut and determinate; if at one instant the muscle is wholly refractory, at the next instant it is not wholly responsive; the refractoriness fades away gradually (through the partially refractory period) and responsiveness gradually develops. The state of refractoriness is found to be denser as it is traced backwards through the cycle until at last it becomes absolute. The development of the partially refractory phase, which is a phenomenon of high rates of beating, expedites the closure of the gap between the end of the absolute refractory period and the end of the cycle. The precise instant at which the state of partial refractoriness ends is not measurable, but it is certain that, as the rate of beating advances, it soon bridges the gap completely. When this stage is reached the cycle is divisible into two—namely, a phase of absolute refractoriness and a phase of partial refractoriness; there is no true or wholly responsive phase. This state of the muscle is represented in a small diagram above the main figure.

The meaning of the change which I have described is not obscure; it is this: when the rate is sufficiently raised the muscle fibres do not all contract during each cycle; some contract in alternate cycles only, and the critical rate at which regular response fails is not the same for all the muscle fibres; some fail to respond earlier than do others. During the phase of absolute refractoriness all the fibres are refractory to stimulation; during the remainder of the cycle the fibres one after another recover their excitability, the muscle as a whole becomes more and more responsive therefore, but up to the very end of the cycle some fibres still remain refractory.

I have dealt with this question of partial refractoriness at some length, because it is essential that it be comprehended fully and clearly. It is a phenomenon which has fundamental influences upon the action of the auricle beating at very advanced rates. What I especially desire to emphasise is that, at these advanced rates of beating, each excitation wave entering the muscle finds that muscle imperfectly recovered from the passage of its predecessor.

Let us apply the small diagram in the upper part of Fig. 1 to our picture of a circulating wave. In the diagrams of the ring experiment shown in the last lecture I represented the circulating wave in its most simple form. The relations there shown between the advancing crest of the wave and its wake of retreat represent what is occasionally found in actual experiment. More usually, however, the relation in flutter is a little more complex. The gap between the crest and wake does not consist of wholly responsive but of partially refractory muscle (see Fig. 2). The onmoving crest encounters many fibres which are responsive; it finds some which are still refractory. These refractory fibres form minute barriers to its progress; it wends its way from side to side, passing only where it finds channels open and ready to receive it. It is as though a second prairie fire followed a first, but followed it at a time when the vegetation formerly burnt had not fully returned to its old condition; there would be places where the cinders of the first fire still blackened the earth, and the second flame in passing would creep around the edge of these before it could go forward. These barriers, by deflecting it, render the onrushing wave sinuous in its course, and delay its progress from point to point.

I said in my first lecture that in flutter the rate at which the wave is transmitted is not usually normal, but that it is slower than normal. We have proof that this delay is not due to change in the rate of fibre conduction, but to small barriers of unrecovered (or refractory) fibres. This observation is one of no little consequence, since it much simplifies our conception of those factors which are responsible for the maintenance of circulating waves. These factors are three—namely, the length of the muscle path, the rate of propagation from point to point, and the duration of the effective refractory period. We now see that the second factor is controlled by the third. In large measure the length of the path is also controlled by the refractory phase; for where several channels are open to the crest of the circulating wave it will take the shortest, and that is the path along which it most closely follows its own wake. In studies of flutter, and in those of fibrillation, refractory period becomes of prime importance. Its length, and especially the length and character of its partial phase, are responsible not only for the maintenance of circulating waves, but, as we shall see, for the particular form of disordered movement which the auricle assumes.

THE PRODUCTION OF EXPERIMENTAL FIBRILLATION.

It has been stated previously that a frequent first step towards knowledge comes when we produce, by experimenting upon animals, a condition identical with that seen in our patients. In so far as fibrillation of the auricle is concerned that step was taken 11 years ago.

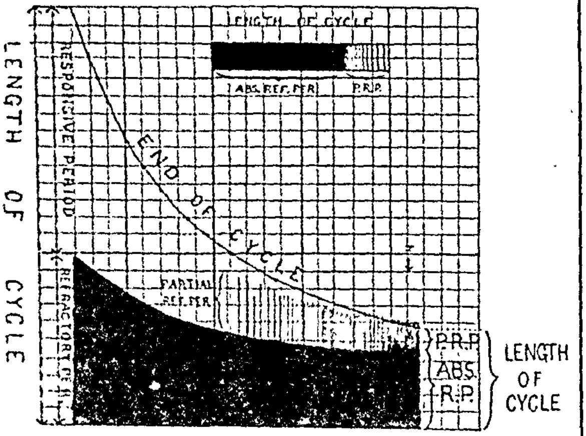


FIG. 1.—The main diagram illustrates the relation of the refractory period to the length of the cycles when the auricular rate is raised by equal increments from its normal rate to a high level. The black portion of the diagram represents the absolute refractory period, which shortens as the rate is raised (that is, reading from left to right); a curved line indicates the shortening of the cycle itself. P.R.P. = period of partial refractoriness. ABS.R.P. = period of absolute refractoriness.

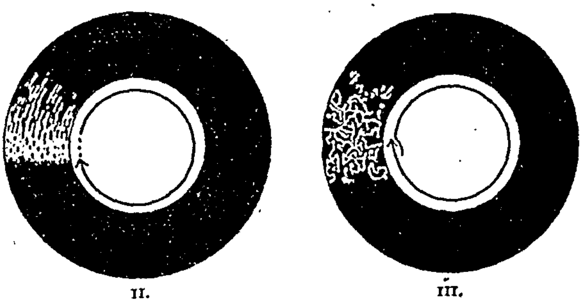
At that time a condition termed fibrillation of the auricles was well known to experimenters, and a common form of disordered heart action was recognised in patients; but neither the experimental nor the clinical condition had been examined sufficiently closely to make it clear that the two states are one and the same. This identity was proved when the electrocardiograms of the experimental and clinical conditions were submitted to close comparison by Rothberger and Winterberg and myself in 1909, and when a little later I sought and obtained the opportunity of exposing to view the heart of a horse suffering from the same malady as do our patients.

Since the time of these demonstrations the term fibrillation of the auricle has come to be used universally in describing this particular disorder of the human heart. In Fig. 4 I show again electrocardiograms of the experimental and clinical conditions. Treated pictorially the curves of auricular fibrillations are, within certain limits, variable; but exactly comparable variations are to be seen in man and animal. The variability of the picture is in large part governed by the action of the ventricles. As you are aware, the rate of the ventricular action is not always the same, neither is the degree of its irregularity in different samples of fibrillation. It is not difficult to choose, from a collection of clinical curves on the one hand and experimental curves on the other hand, examples in which the resemblance is so close as to be convincing. With the details of the curves I need not now detain you, but would remind you of their most constant features. The ventricular representatives (*R* and *T*) are frequent and irregularly placed; the auricular representatives comprise a series of oscillations, of irregular form and somewhat irregular incidence and amplitude. The auricular representatives in flutter are united end to end; the action is quite regular and continuous and its mean rate is approximately 300 per minute. The auricular representatives in fibrillation are not very dissimilar to these; they are also joined end to end, and the action is again continuous. The auricular action in flutter and fibrillation differs, however, in important respects; thus, in fibrillation it is 50 per cent. faster, the oscillations having a mean rate of about 450 per minute; another difference is that in fibrillation the cycles are not accurately repeated, sometimes over short stretches of curve there may be at least a suggestion of repetition (as in the last record of Fig. 4), but close measurement will show that it is not precise; moreover, it is not long maintained. Change is the rule.



II. III.

FIG. 2.—A schematic representation of the excitation wave as it circulates in flutter. The blackened portions of the ring represent those portions of the muscle which are refractory at a given instant. The crest of the wave travels constantly through muscle in a partially refractory state. The border of the advancing wave is finely serrated.

FIG. 3.—A similar representation of the excitation wave as it circulates in fibrillation. The advancing border and retreating wave are deeply crenated, and these crenations overlap. The wave is constantly advancing through small and irregular channels of responsive tissue as these open up to receive it.

THE NATURE OF FIBRILLATION AND ITS RELATION TO FLUTTER.

I have pointed out that the first step in this inquiry was taken 11 years ago, when it was ascertained that the clinical disorder is identical with one which can be produced experimentally; but it is to be understood that we then obtained no close insight into fibrillation *quâ* fibrillation. We had obtained knowledge of a disorder of the human heart, and, more important, the means of further investigating it. It is in respect of these further investigations that I shall now speak. The method of research has been very similar to that employed in the case of flutter. We produce fibrillation of the auricles in an animal by suitable stimulation, and proceed to examine the paths taken by the excitation waves through the muscle while this fibrillation continues. It would be impossible for me to place before you in this lecture the details of this analysis; I can only attempt to acquaint you with the chief conclusions at which we arrive after fully considering the evidence derived from all sources. The main conclusion is that fibrillation, like flutter, is maintained by a circulating wave. As in flutter, the central circulating wave is a single wave, but the circuit is completed in a shorter time; the auricular cycles, therefore, follow each other more quickly. To what is this quicker movement due ultimately? It is almost certainly due to the path of the circus movement being somewhat shorter than is the case in flutter. Why should the path be shorter? Probably because in auricles predisposed to fibrillation the effective refractory period is shorter than in those predisposed to flutter. The crest of the circulating wave in both conditions tends to follow close upon its own wake. The refractory muscle forms a ring broken by a small gap; this broken ring, regarded as a whole, revolves. *Now the length of refractory tissue* in this ring at any given instant is obviously controlled by the duration of the refractory *period*. A decrease in the refractory period shortens the length of the tissue involved in this state at any given moment; consequently, if the gap remains unaltered the diameter of the ring must shorten. If a snake glides along the path taken by its own tail the size of the circle which it inscribes will be controlled by the length of the snake.

We believe that in fibrillation the circuit is smaller in diameter than in flutter. We cannot yet describe with confidence the precise paths which are followed, but there is some direct evidence to suggest that the mouth of the superior cava is one of the circuits which the central wave favours. Where precisely the circuit is situated is of little moment. To recognise that a single circuit exists should suffice.

The difference between fibrillation and flutter is in part one of rate; but that is not the sole difference or even the most important difference. It has been shown to be the rule that in flutter the crest of the circulating wave is constantly passing through tissue in a partially refractory state. The wave as it progresses strikes upon small barriers which render its course finely sinuous. In fibrillation this interference is much exaggerated; the barriers are larger and the crest travels along paths coarsely sinuous. Seemingly, the crest has not a straight or simply curved border of advance; it is deeply and irregularly crenated. Its wake is similarly crenated, and the crenations of the one and the other overlap and intertwine; this relation is shown diagrammatically in Fig. 3. The crest of advance moves through muscle, apparently in a denser state of partial refractoriness than is the case in flutter.

Picture the path travelled by the wave after it has circulated several times in flutter (*Fig. 5*). There is the track of the central re-entering wave; the path taken is finely sinuous, but apart from these very minor variations it is constant. As this mother wave circulates in the main channel it throws off centrifugal waves at each revolution, and these proceed into outlying areas of the muscle, such as the appendices and the sleeves of muscle on the cavæ; along these outlying channels the path is also finely sinuous, but in general constant. The whole muscle of the auricle is involved in each cycle. With each revolution the events are repeated; the waves are signalled with almost perfect regularity in every part of the musculature; at each revolution a wave passes to the region of the *a–v* node, the responses of the ventricle are, therefore, of an orderly character.

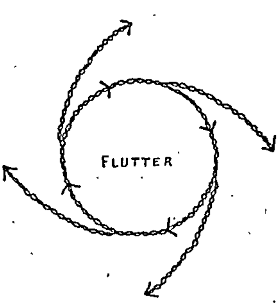


FIG. 5.—A diagram illustrating the successive paths followed by the excitation wave in flutter. The path is finely sinuous, but is in general accurately repeated from cycle to cycle.

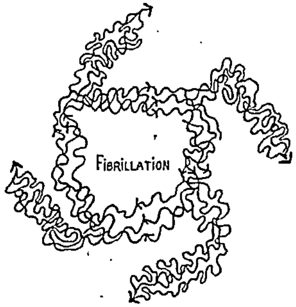

FIG. 6.—A similar diagram of the successive paths taken in fibrillation. The path is coarsely sinuous and ever-varying, though it continues to progress in a clockwise fashion around a central area.

Picture similarly the path which the wave has followed after it has circulated several times in fibrillation (Fig. 6). Everywhere the track is coarsely sinuous. There are the central tracks, spread over a wider band of tissue than in flutter,[1] because the path varies. Speaking very broadly, the same central path is trodden over and over again, but in detail there is no constancy. The wave may, and apparently *does*, encircle the same central area repeatedly if not continuously, but it staggers along its course; it is a road of many and serious obstacles. For that reason it does not return *to its starting point after constant* intervals of time; for that reason *and because of change in the actual* path pursued, the oscillations in the electrocardiograms are of irregular incidence and form. The *paths through the outlying muscle also* vary. Place contacts on any region of the auricular muscle and the waves are not signalled regularly as in flutter, but irregularly; a few even fail *to arrive at their proper destinations. With each irregular* revolution, or at least with most, a wave passes to the region of the *a–v* node.[2] These waves arrive at the node

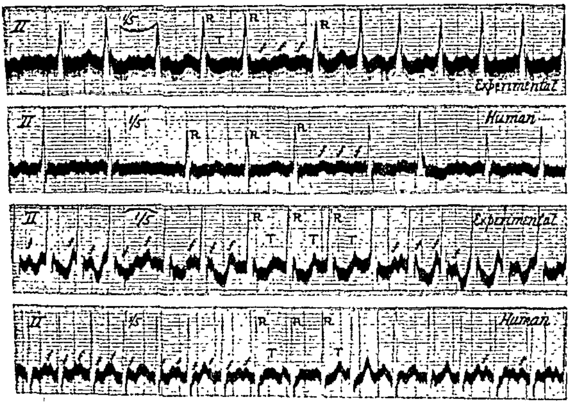

FIG. 4.—Four electrocardiograms (lead *II*) illustrating fibrillation of the auricles in man and the dog. The first and third curves are from dogs, and have been taken from recent experiments in which fibrillation of the auricles has been analysed. These two curves should be compared with the second and fourth respectively; these last are examples of clinical fibrillation. R and T are ventricular deflections; *f f* are the oscillations *arising from the fibrillating auricles.*

---

[1] Though the band of tissue involved in successive circuits is wider, the average circle is probably of lesser diameter, as already stated. The shorter diameter is not represented in the accompanying diagram.

[2] The waves which reach the *a–v* node are approximately one-tenth less numerous than those which flow along the central path. In the average they number, therefore, about 400 per minute in human fibrillation.

more frequently than they do in flutter, for the general movement is somewhat faster; but because the path travelled is coarsely sinuous and variable they arrive at the node irregularly. The responses of the ventricle are therefore irregular.

THE ACTUAL CIRCUITS IN FLUTTER AND FIBRILLATION.

A single circulating wave is responsible both for flutter and for fibrillation of the auricle; in both conditions it follows the re-entrant path repeatedly, though in flutter this repetition is far more exact than it is in fibrillation. We possess some definite knowledge of the actual paths followed by the wave in the fluttering auricle of the dog. The wave may encircle the mouth of the superior cava and includes a variable amount of tissue lying between this vessel and the inferior cava, or it may encircle together the mouths of both superior and inferior vena cava; it is probable, though it is not proven, that circuits are formed in some instances around the auriculo-ventricular orifices.

In man the rates in flutter are from 240 to 350 per minute; in the dog the rates are 345 to 580 per minute. In other words, the rates in the dog are approximately 50 per cent. faster. Difference in the size of the organ in man is sufficient to explain this difference of rate, if we assume the rate of transmission in the human and canine auricles to be equal. We may arrive at a general, if we cannot arrive at a precise, idea of the ring's circumference in the human subject. Thus, if the rate of a human flutter is 240 per minute, the duration of each cycle is 0·25 of a second; if the rate is 350 per minute, the duration of each cycle is 0·17 of a second. Assume that the transmission rate in flutter is 500 mm. per second, then the length of the path will be 125 mm. in the one case and 85 mm. in the other, and the diameters of the corresponding circles will be 4 and 2·7 cm. respectively. Thus, if our assumed transmission rate is correct, the circular paths in flutter are of diameters somewhat exceeding the diameters of the chief orifices of the auricle. It is these natural orifices to which we look, especially in attempting to locate the actual paths of the waves.

In human fibrillation the rate of movement is faster; it lies usually in the neighbourhood of 450 per minute, the cycle having a duration of 0·13 of a second. If we assume the same transmission rate, then the length of the path would be 66 mm., and the diameter of the circle would be a little more than 2 cm. It will be evident that if this estimate is approximately correct, and if we suppose that the chief orifices of the auricle to be those encircled by the waves in fibrillation, that in this last condition the encirclement must be a very close one. The factor which remains in doubt is, of course, the rate of transmission.

The subject of possible remedies for the state of affairs which I have described is still unripe for discussion; perhaps I have said enough in indicating what seems to me one of the chief lines which investigation should take: it is an investigation of the refractory period of heart muscle, a search for remedies which will influence the duration of this refractory state, and which, by prolonging it, will help us to close the gap between the crest and wake of the circulating wave; for this gap is essential to the maintenance of the circulating wave, whether the circulating wave is responsible for flutter or for fibrillation.

Finally, the lecturer proceeded to demonstrate shortly his recent experiments with Dr. Drury and Dr. Iliescu upon the movements of the electrical axis of the auricle in clinical flutter and fibrillation. If suitable planes are chosen it can be shown, in both these conditions, that the electrical axis changes its direction in a definite and striking manner: it revolves through 360° as each auricular cycle is completed. As the electrical axis may be taken as an index of the general direction in which the wave is travelling, these observations demonstrate that in flutter and fibrillation the wave travels in a circular fashion through the auricle. Taken conjunction with the experimental evidence, they stitute proof of simple circus movements in the an auricle affected by these two disorders.

—Full references to the work on flutter and fibrillation will ind in the original papers published in *Heart*, Vols. VII. VIII.

PERMANENT DRAINAGE OF THE ONLY KIDNEY.

BY WILLIAM HENRY BATTLE, F.R.C.S. ENG.,
CONSULTING SURGEON TO ST. THOMAS'S HOSPITAL, ETC.

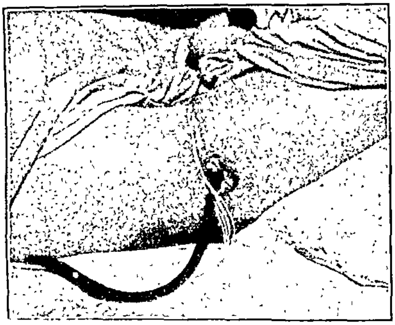
IN April of last year I was asked to see again a girl of 23 years of age who had been in St. Thomas's Hospital five years previously, and for whom I had performed an operation on the kidney. When she presented herself for examination it was difficult at first to believe that the operation which was mentioned as having been performed was correctly stated. The girl was of good colour, well developed, walking with ease, and had recently completed a period of four years' work in a munition factory. Her father, who lived in South Africa, was anxious to take her back with him if it was considered she would not be any worse for living in a warm climate; he also wished to know if a silver tube which she was wearing could be dispensed with. This tube was placed in the left loin, and all the urine which she passed came away through it, being then conveyed along a rubber tube to a rubber receptacle over the left hip. No urine was passed from the bladder. Her general health was good, but she had at times "a feverish cold," with some pain in the kidney region, and then the urine was cloudy; as a rule it was quite clear. Occasionally she had a pain in the left groin, especially in damp weather. Catamenia absent.

Examination showed that there was a silver tube about 1/3 in. in diameter and 4 in. long placed in the centre of a scar below the left lower ribs. This scar was that usually seen after the incision employed for nephrotomy. The skin around was healthy, dry, and without any trace of irritation. There was no leakage by the side of the tube, which was removed, cleaned, and easily replaced daily. A slight bend in the middle appeared to make the tube adapt itself exactly to the sinus in which it was placed. There was no urinous odour.

Mr. C. A. R. Nitch kindly admitted her to St. Thomas's Hospital for a few days when the photograph was taken. She was examined by the X rays, but nothing in the way of phosphatic concretion was shown in the pelvis of kidney or ureter, and the urine was quite normal. There was no ureteral opening on the right side on cystoscopic examination, nor was it possible to pass a catheter far along the left ureter. This confirmed the statement that she had only one kidney.

Previous History.

The previous history of the case was that she had undergone an operation at the end of 1911 for double uterus with complete septum, and retention of the menses in the closed right half. The patent half was pushed over to the left and the right half distended, forming a cystic swelling to the right and behind. The cervical canal was opened up from below, the uterus split, the septum cut out, and the two halves sutured together. She came under the care of Dr. J. S. Fairbairn in St. Thomas's Hospital in 1914. The operation had not been a success so far as the preservation of the uterus was concerned owing to the pooling of the discharges in the pouched and dilated half of the uterus and cervix. An exceedingly offensive discharge, especially at the menstrual periods, occurred, and in spite of dilatation and disinfection of the cavity of the uterus infective endometritis, followed by pelvic inflammation, necessitated a further abdominal operation—removal of uterus and tubes. An abscess was found in front of the uterus in the utero-vesical fossa and also behind the uterus. Difficulty was met with owing to the stretched condition of the cervix and lower part of the uterus, especially to the right. The softened bladder wall in the region of the abscess gave way whilst being pushed from the cervix and a vesico-vaginal fistula followed. This operation was done on Dec. 23rd, 1914. On the next day no urine was passed, but on the following day some came both from the bladder and from the abdominal wound. By Jan. 31st, 1915, she was well enough to return home, but was readmitted on Feb. 15th complaining of pain and tenderness about the left kidney which commenced six weeks earlier. This was associated with a rise of temperature. *Bacillus coli* was present in the urine. On March 9th she had a rigor with rise of temperature to 105·6° F. I was then asked to see her and operated the same day, placing a large drainage-tube in the renal pelvis, which was much distended with purulent urine. The renal pelvis was freely opened. The tissues round the kidney were matted and the capsule adherent. It was not attempted to suture the edges of the renal pelvis to the skin. After the 23rd there was no more urine passed by urethra—all came by the loin tube—and it was evident that she had only one kidney. The urine became clear by the 23rd and the symptoms of pyelitis passed away, but there was still some pus coming from the bladder. A retro-vesical abscess was opened at a later date, and she left the hospital June 21st, 1915, still wearing the rubber tube, through which all the urine was passed. Later, a silver-flanged tube was substituted for the rubber one for regular use, and kept in position by tapes passing round the waist.



Five years after operation: No irritation of skin. Tube in left loin with flange through which supporting tape is passed.

(See figure.) This tube fits closely at a point corresponding to the lumbar fascia, but is easily taken out and replaced by the patient's mother.

The Operation of Choice.

This case goes far to show the superiority of the operation of nephrotresis as the one of choice when the ureter has been badly injured and the circumstances make it impossible to re-establish the channel by any method of ureteroplasty. There were only two methods available here because the injury had been at a point deeply placed in the pelvis, and the amount of cicatricial tissue about it prevented the possibility of a successful search for the lesion. If such a search had been made and by some chance the injury could have been repaired, obstruction would have ensued later from the surrounding scar tissue as it contracted: This with a condition of pyelitis affecting what proved to be the only kidney would have been fatal. In the experience of many surgeons the operation of bringing the end of a divided ureter out on the skin of the loin and fixing it there is unsatisfactory. The flow is apt to become impeded by contraction of the orifice, whilst the urinary tract above becomes infected even in clean cases, so that a state of pyonephrosis with fever develops. This sooner or later necessitates removal of the kidney when the patients have a second which is healthy. This girl had already pyelitis with early dilatation of the renal pelvis, so it was imperative that the drainage should be free from the first. In addition, it is difficult to adjust an apparatus which will act efficiently when the ureter is brought up, so as to prevent irritation of the skin with constant wetting of the patient's clothing and a very annoying urinous odour.

The operations necessitated by the congenital deformity of the uterus were difficult, and the inflamed tissues prevented recognition of the position of the ureter, which quite possibly was *not* in its normal place. The improvement in the girl's health which has ensued on these operations is very great, for the constant offensive discharge, with local septic inflammation, was producing a state of chronic invalidism and unhappiness.

RESEARCHES ON THE BIOCHEMISTRY OF GERMS AND OTHER PROTEINS,

WITH SPECIAL REFERENCE TO THE PROBLEMS OF IMMUNITY.

BY DAVID THOMSON, O.B.E., M.B., CH.B. EDIN., D.P.H. CAMB.,
LECTURER AND RESEARCH PATHOLOGIST, LONDON LOCK HOSPITAL; DIRECTOR OF THE BIOLOGICAL RESEARCH LABORATORY, GENATOSAN, LTD.

(*Concluded from p. 798.*)

PART II.—PREPARATION OF DETOXICATED VACCINES.

1. *Preliminary Note.*

ONE is naturally led by the foregoing to conclude that a detoxicated vaccine containing all of these fractions might be better than my original vaccine, which contained only the alkali-soluble non-toxic component.

2. *Preparation of Detoxicated Vaccines Containing all the Antigenic and Non-toxic Portions of the Germs.*

In order to detoxicate a germ so as to prepare a vaccine which shall contain all of the antigenic and non-toxic components it is necessary to isolate each component separately by successive stages. When isolated they are mixed together in the same proportions as in the given germ itself. This mixture, emulsified in normal saline solution containing 0·5 per cent. carbolic acid to keep it sterile, is then standardised to a strength suitable for injection into the human subject.

Stage 1. Isolation of the alkali-soluble substance.—A mass of the given germ amounting to 5 or 10 c.cm.† of moist semi-solid material is collected in a graduated centrifuge tube; to it is added about an equal volume of N/1 NaOH (in the case of easily soluble germs) or of antiformin (in the case of germs which dissolve with difficulty). The material is thoroughly mixed with the aid of a glass rod, and is then placed in the incubator at 37·5° C. for about three hours. The mass of germs plus alkali will gradually dissolve into a more or less transparent or semi-transparent fluid. In some cases this takes place in a few minutes, in others it requires several hours; three hours is usually sufficient. With certain germs, such as staphylococci, the dissolved mass often sets into a semi-solid transparent jelly, more especially if it is allowed to stand in an ice-chest. As soon as the action of the alkali has dissolved or disintegrated the germs the mixture is filtered through a fine filter paper. When the material is syrupy or gelatinous in consistence it is necessary to mix it thoroughly with some water in order to render the filtration process more easy. The filtrate is a clear yellowish fluid, and represents the alkali-soluble fraction of the germ.

Stage 2. Isolation of the acid-soluble substances.—The alkali-insoluble material is now washed off the filter paper with N/1 HCl into another tube, and after thorough mixing with the acid is allowed to stand in the incubator for a few hours. This mixture is again filtered. This filtrate represents the acid-soluble fraction.

Stage 3. Isolation of the alcohol-soluble substance.—The material left on the filter paper is washed off with absolute alcohol, and after standing in the incubator for a few hours is filtered. This third filtrate contains the alcohol-soluble component.

Stage 4. Isolation of the chloroform-soluble substance.—The material left on the filter paper is washed off with chloroform placed in the incubator as before and again filtered. This filtrate represents the chloroform-soluble component.

Precipitation of the four components from their respective solutions.—The original germ mass has now been dissolved into four fractions, each contained in a different tube. The next step in the detoxication process consists in precipitating each fraction from its respective solution as follows:—

(1) *Precipitation of the alkali-soluble fraction.*—To the tube containing the alkali plus alkali-soluble material add N/1 HCl until precipitation begins. Now add the acid drop by drop until the maximum amount of precipitation has occurred. It is possible to add too much acid, since the precipitate sometimes tends to be soluble in excess of HCl. The tube is now centrifuged at high speed for several minutes. The amount of deposit is measured and kept, and the supernatant fluid which contains proteoses is poured off into another tube and also kept for further treatment. See below under (5).

---

† It is scarcely practicable to deal with quantities less than 5 c.cm

(2) *Precipitation of the acid-soluble fraction.*—To the tube containing the acid plus acid-soluble material add N/1 NaOH until the resultant fluid is definitely alkaline to litmus. A light flocculent precipitate is produced which does not tend to dissolve in excess of alkali. The tube is now centrifuged as before. The deposit is separated from the supernatant fluid, both components being kept for further treatment. (For recovery of the proteose from supernatant, see under (5)).

(3) *Precipitation of the alcohol-soluble-lipoid substance.*—To the tube containing the alcohol plus the alcohol-soluble germ substance add twice the volume of normal saline; a very fine precipitate is produced. Allow the tube to stand for one or more days until the fine precipitate flocculates into larger masses. When this has occurred filter, wash the precipitate off the filter paper with saline, and add 0·5 per cent. carbolic acid to keep it sterile.

(4) *Precipitation of the chloroform-soluble constituent.*—Place the tube containing the chloroform plus chloroform-soluble fraction in a drying oven, and when the bulk has been considerably reduced by the evaporation, add excess of absolute alcohol. The alcohol throws the chloroform-soluble material out of solution. Centrifuge and collect the deposit.

(5) *Precipitation of the proteoses.*—The supernatant fluids obtained after the precipitation of the alkali and acid-soluble fractions were kept as mentioned under (1) and (2). After bringing these fluids to a neutral reaction add twice their volume of absolute alcohol and allow to stand for about 12 hours. The proteoses separate out and can be driven down in the centrifuge.

N.B. *Toxic filtrates and supernatant fluids.*—The saline alcohol filtrate obtained in (3), the alcohol chloroform filtrate obtained in (4), and the alcoholic supernatant fluids obtained as in (5) should be kept for further examination, since they contain toxic substances, a fact which will be discussed later. For more complete detoxication the precipitates obtained as under (1), (2), (4), and (5) should be washed twice with fresh absolute alcohol, and the toxic alcohol washings kept for further investigation. The precipitate obtained as under (3) cannot be washed with alcohol, but should be washed with sterile water; by "washing" I mean that each precipitate is thoroughly mixed up with the alcohol or water and then centrifuged or filtered. This process is repeated twice.

Collection of the non-toxic precipitates and standardisation of the vaccine.—The five different precipitates obtained from the original mass of germs by the above process include the alkali, acid, alcohol and chloroform-soluble substances, and also the proteoses. These wet precipitates are now collected into a graduated tube and centrifuged at about 3000 revolutions per minute for a period of two minutes, after which the total bulk is estimated. The mass of precipitate is now transferred to a small flask or bottle containing glass beads. Add 50 c.cm. of normal saline + 0·5 per cent. carbolic acid and shake very thoroughly until a fine and uniform emulsion is produced.

I have estimated by Wright's method of counting bacteria that a mass of 1 c.cm. of semi-solid wet gonococci (centrifuged at about 3000 revolutions for two minutes) contains about 1,250,000,000,000 cocci. If this mass therefore be emulsified and made up to 125 c.cm. with saline, each cubic centimetre of the emulsion will contain 10,000 million germs. This is the normal strength to which I standardise a detoxicated vaccine—viz., 10,000 millions per cubic centimetre. It is not quite accurate to standardise a detoxicated vaccine according to the volume of wet semi-solid germs originally dealt with, since some of the material is lost during the detoxication process. For example, one might begin with 5 c.cm. of the original germ mass and end up with only 4 c.cm. of the non-toxic precipitates. In view of this fact I standardise the vaccine according to the volume of the precipitates obtained. Each cubic centimetre of precipitate is made up to 125 c.cm. with normal saline + 0·5 per cent. carbolic acid, the resulting emulsion is designated as representing 10,000 million germs per cubic centimetre. No doubt it would be more accurate to standardise the vaccines according to the weight of the dried precipitates rather than according to the bulk of the wet precipitate. The former method, however, is tedious and is impracticable in the case of autogenous vaccines, where the amount of germ substance dealt with is comparatively small.

It is hardly possible to standardise detoxicated vaccines by judging the opacity of the emulsion against a known standard, as is usually done in the case of ordinary vaccines. If this method was used very wide errors would result because the proteoses largely dissolve in the saline, forming a transparent solution. In consequence detoxicated vaccines made from germs containing a high percentage of proteose, as is found in the *B. coli*, typhoid, and dysentery group, would appear, according to the opacity test, very much weaker than those made from, say, the staphylococcus group, where the proteose content is very low.

3. *Investigation of Toxic By-products Obtained in Detoxication of Germs and Other Proteins.*

The toxic by-products of the germs are to be found in the various alcoholic filtrates, supernatant fluids, and washings obtained from the precipitates in the detoxication process just described. These alcoholic fluids are usually of a light yellow or straw colour. They contain peptones, amino-acids, salts, indicators, fatty acids, &c.

I should here mention that if a mass of minced meat or other tissue is put through the same process as just described for the detoxication of germs the same component precipitates are obtained. Moreover, the waste alcoholic filtrates and washings are toxic, yellowish in colour, and appear to be more or less similar to those obtained from the germs. Indeed, all the facts obtained in the parallel researches which I have carried out with germs, on the one hand, and with animal tissues on the other, go to prove conclusively that germ-protoplasm and animal tissue are very closely allied in their physico-chemical composition.

V. C. Vaughan[18] was apparently the first to note that germs and all other protein substances, whether animal or vegetable, could be split up into a toxic and a non-toxic portion. The toxic portion, a brownish substance with a characteristic pungent odour, he found to be soluble in absolute alcohol. He believed it to be more or less identical in all proteins. When injected into animals it killed them in a manner which suggested anaphylactic shock, and he attempted to prove that this toxic substance was in all cases the cause of anaphylaxis.

Vaughan's Method of Extracting the Poison from the Germs and Other Proteins.

(1) The mass of bacteria or other protein is thoroughly washed with alcohol, beginning with 50 per cent. and increasing to 95 per cent.

(2) The substance is placed in large Soxhlet's flasks and extracted first for one to two days with absolute alcohol, and then for three or four days with ether. These extractions with alcohol and ether should be thorough in order to remove all traces of fats and waxes.

(3) After extraction the cellular substance is ground first in porcelain and then in agate mortars, and passed through the finest meshed sieves. This finely ground cellular substance, in the form of an impalpable powder, may be kept in wide-mouthed bottles in a dark place, and if so kept retains its toxicity for years; when exposed to light, and even if kept perfectly dry, it becomes less poisonous. Therefore, although the toxic substance is soluble in alcohol it is not extracted from the germs or protein substance even with prolonged boiling with alcohol and ether. Vaughan points out that before the poison can be extracted by the alcohol the protein must first be disrupted or split up.

(4) The poison is extracted from the bacterial or protein powder by boiling it with from 15 to 25 times its weight of absolute alcohol, in which 2 per cent. sodium hydroxide has been dissolved. After boiling for an hour on a water bath the alcohol is filtered off, and is found to contain a large amount of the poison. Three such extractions were found necessary in order to split off all the poisonous group.

(5) The non-toxic residue after extraction is dried into a fine powder. The toxic alcoholic fluid is evaporated to dryness, and the toxin thereby obtained is reduced to the form of a fine powder.

Vaughan found in the case of *B. coli* that 20 mg. of the bacillary powder, before extraction of the toxin, was the minimum lethal dose, whilst the minimum lethal dose of the non-toxic powder was as high as 300 to 400 mg. This non-poisonous residue was therefore 15 to 20 times less toxic than the actual bacillary powder before extraction. The minimum lethal dose of the powdered toxic material extracted by the alcohol varied from 8 to 60 mg. according to its state of purity. From inoculation experiments carried out on guinea-pigs and rabbits Vaughan concludes that no immunity is developed against the toxic substances extracted from *B. coli* or other germs. With repeated injections the animals developed at the most only a small degree of tolerance. Definite immunity was, however, obtained after repeated injections of large doses of the *B. coli* powder from which the toxin had been extracted. The guinea-pigs so injected acquired an active immunity, so that they could withstand at least eight times the fatal dose of the living germ.

Comments on Vaughan's work.—I was unaware of the existence of Vaughan's valuable researches until the end of 1919, when I read his work with great interest. My researches have confirmed and coincided with his in many points. It is interesting to note that whilst his work was directed mainly towards the toxin and the cause of anaphylaxis, mine has been directed mainly towards the antigenic values of the non-toxic components, with the desire to develop and produce more perfect vaccines and more perfect immunity.

It seems to me remarkable that Vaughan and his co-workers did not appear to realise the importance of their work in its application to vaccines and practical therapeutics. In this respect they went no further than to carry out some inoculation experiments on animals, and no therapeutic inoculation experiments on human beings were recorded. Perhaps his non-toxic bacillary residues were tested in this respect and found to fail; I do not know if this was the case. At any rate, it appears to me that his process of removing the toxin must remain unsatisfactory from the point of view of producing non-toxic vaccines, since the prolonged application of heat is injurious to the antigenic properties of the non-toxic substances. My experiments have shown that boiling at 100° C. for half an hour largely destroys the antigenic properties of the gonococcus as estimated by the complement-fixation test. For this reason my detoxication process is carried out quickly at a temperature no higher than blood heat. On the other hand, it will be noted that Vaughan's process of removing the poison entails a temperature of 78° for one to two days and a further heating for three or four days (during the preliminary alcohol and ether extractions for the removal of the fats and waxes). Finally, there is an extra heating to 78° for three hours during the actual extraction of the toxin with alcohol and alkali. This continued heating for a period of five or six days must, according to my experiments, have a very marked deteriorating effect on the antigenic properties of any antigens prepared by his process.

Physical characteristics of the toxin.—According to Vaughan, the toxic substance, when more or less purified and dried into powder form, has the following characteristics:—

(1) It is a brownish powder.

(2) It is highly hydroscopic and freely soluble in water. Any portion of the powder which did not dissolve in water was found to be non-toxic.

(3) Aqueous solutions of the poison are decidedly acid to litmus. When a few drops of mineral acid are added to this aqueous solution a precipitate is produced. Vaughan believes that this precipitate is caused by the presence of some organic acid, and he considers this organic acid to be the cause of the acidity in the aqueous solution of the poison.

(4) When the aqueous solution of the toxin is neutralised with sodium bicarbonate a brownish non-toxic precipitate is formed.

Prolonged contact with alkali lessens the activity of the poison, and even neutralisation has this effect, which is more marked the longer the preparation stands. Vaughan is inclined to attribute this to the formation of a salt through the interaction of the acid poison and the alkali. It is interesting to point out here that M. H. Gordon[16] observed that NaOH, more especially when concentrated, tended to destroy the endotoxin of the meningococcus.

(5) The toxin, according to Vaughan, is more freely soluble in alcohol than in water. Alcoholic solutions were kept for five years without recognisable loss in toxicity. It is soluble in methyl as well as in ethyl alcohol, and insoluble in ether, chloroform, and petroleum ether. Each of the latter removes a small amount of fatty substance, which is non-toxic, but they do not dissolve any appreciable quantity of the poison itself. From its alcoholic solution the poison is precipitated by ether, but contact with ether decreases its toxicity to such an extent that this method is not applicable in attempts to purify the poison.

(6) The poison diffuses slowly through collodion sacs both within the animal body and when suspended in distilled water.

(7) Vaughan considers that the poison is either a protein itself or else is mixed with one or more proteins. In aqueous solutions it gives all the protein colour reactions with the exception of Molisch's test. The Millon reaction is the most characteristic; it gives the biuret, the glyoxylic acid, and the xantho-proteic reactions, and also reacts to Liebermann's test, but does not reduce Fehling's solution. Other tests indicate the presence of sulphur in the substance.

(8) Phosphotungstic, phosphomolybdic, and picric acids all give abundant precipitates, but after much careful analysis Vaughan and his co-workers concluded that the poison was more of a protein than of an alkaloidal nature.

Preliminary Investigations on the Toxic Extracts by the Author.

My researches on the toxic extracts obtained from various germs in the detoxication process described in paragraph 2 of this part of the paper are still far from complete. In the first place, this side of my research has been retarded by the difficulty and delay in obtaining a vivisection licence for the laboratory in which I had been working. Furthermore, the actual amount of concentrated toxic material obtained from a mass of germs is very small. I have been collecting this material for nearly two years, so that only now do I possess a quantity sufficient for a thorough investigation.

(1) *Method of Concentrating the Toxic Material.*

The toxic, straw-coloured, alcoholic, supernatant fluids and washings from the germ precipitates are placed in a flask and heated on an electric plate or water-bath in order to drive off the alcohol and concentrate the fluid. When all the alcohol has been boiled off the watery fluid left in the flask has a deep reddish-brown colour. This is transferred to an evaporating dish and dried in a drying chamber until only a semi-solid, moist residue remains. This residue, dark brown in colour, contains numerous crystals of NaCl, &c., and has a peculiar offensive odour. The mass, which is alkaline in reaction, is ground up thoroughly with about twice its volume of absolute alcohol, and then acidified with a few drops of concentrated HCl. The mixture is centrifugalised, and the crystalline material thereby separated from the reddish-brown solution of the toxic substance. The latter may be collected and concentrated still further by a repetition of the same process. This concentrated brownish, toxic material behaves as Vaughan has observed, being soluble in water and in alcohol and reacting to the protein tests which he has described. It is precipitated by picric acid, phosphotungstic acid, &c.

(2) *Presence of Indicator Substances in the Toxic Extracts.*

About two years ago I was greatly puzzled by the peculiar colour effects produced when certain germs were dissolved in alkali, and more especially in antiformin. When Friedländer's bacillus is dissolved in antiformin a deep green colour like crême de menthe is usually produced. This colour is somewhat evanescent and tends to disappear on standing, but when the germ solution is vigorously shaken up with air the colour often returns; the addition of a trace of permanganate of potash also tends to bring back the vivid green tint. Antiformin, by virtue of the chlorine it contains, is an oxidising agent, and it would appear from these facts that the green colour just described is produced by the oxidation of some protein product or by-product of the germ. Later I discovered that this colour substance was a true indicator and soluble in alcohol as well as in water. When a green alkaline solution of the Friedländer bacillus is acidified so as to throw down the meta-protein the colour changes to red and the precipitate produced has a reddish tinge. This red precipitate when treated with alcohol is more or less whitened, and the red colouring matter passes into the alcohol. The alcoholic solution of the colour material changes to green or red according as it is made alkaline or acid in reaction. This peculiar green-red indicator is apparently very unstable, since it gradually bleaches under the influence of light; moreover, if one attempts to concentrate the alcoholic solution by heating it on a water-bath the colour entirely vanishes. This green-red indicator is quite commonly found when germs are dissolved in alkali or antiformin. It occurs most often with Friedländer's bacillus, *Bacillus pyocyaneus*, Pfeiffer's influenza bacillus, various sarcinæ, and the tubercle bacillus.

A rare indicator which is amethyst or blue in colour when alkaline and apparently colourless when acid is occasionally observed during the detoxication of the gonococcus. The most common indicator appears to be of a turmeric nature, showing a brown colour when alkaline and a yellow colour when acid. This turmeric-like indicator is apparently present in all germs and in all proteins. At any rate, it has always been present in alkaline solutions of the germs and other proteins with which I have worked. I am inclined to believe that this indicator, or at any rate its parent substance, is actually present in the bacteria and in the animal and vegetable tissues, and that it is not entirely produced from the protein as a by-product due to the hydrolytic action of the alkali.

For example, if we dissolve turmeric root in alkali and then add absolute alcohol a precipitate is thrown down leaving a large amount of the turmeric indicator in the alcoholic supernatant fluid. If the precipitate is redissolved in alkali and precipitated with alcohol several times the alcoholic supernatant fluid finally becomes clear, and no more turmeric can be obtained even if the precipitate is kept in alkaline solution for several weeks. This would appear to show that a certain amount of turmeric can be obtained from the actual protein and that no more is produced by prolonged action of the alkali.

Since the turmeric and the other indicators described above are soluble in alcohol it is apparent that these colour substances will be extracted in the detoxication process of the germs, and will appear in the toxic alcoholic extracts. The green indicator is destroyed in the concentration process when boiling off the alcohol, but the turmeric material remains and is partly responsible for the brownish colour of the concentrated alcoholic solution of the toxin. From lack of vivisection facilities I do not yet know whether the actual indicator substances described above are toxic in nature or not; this point can only be tested by animal experiments. The amount of turmeric-like indicators produced from different proteins varies to a wide extent. A large quantity can be obtained from milk, and only a comparatively small quantity from meat, such as muscle or ox heart. A very large amount can be obtained from ordinary agar-agar. If agar is boiled with N/1 HCl and then excess of NaOH is added, a deep brown colour is produced which is found to be due to an indicator substance like turmeric. This substance inhibits the growth of the gonococcus. It is very soluble in acid acetone and in water.

I have stated that the reddish-brown alcoholic solutions of the toxic substance from various germs and proteins contain a turmeric-like indicator; the amount present is comparatively small, and the reddish-brown colour of the alcohol-toxic extracts is due, not so much to the presence of the indicator as to some other unknown colouring substance which does not behave like turmeric. These toxic alcoholic extracts show a reddish port colour when acid, and when alkaline the colour is more brownish, like sherry. The presence of the turmeric-like indicator is revealed by shaking up the toxic acid watery alcoholic extracts with ether, chloroform, or acetone. The ether, chloroform, and acetone in all cases become yellowish in colour, changing to brown with the addition of alkali. The bulk of the toxic extract is precipitated by the ether, chloroform, or acetone, only the turmeric fraction remaining in solution.

When the watery alcoholic toxic extracts are subjected to electrodialysis a yellow turmeric-like substance passes through the parchment to the positive pole, whilst a blackish-brown substance (not an indicator) passes to the negative pole. The yellowish material in the positive pole chamber is an indicator behaving like turmeric, whilst the blackish-brown material in the negative pole chamber does not behave as an indicator.

The effect of hydrogen peroxide and ozone on the concentrated toxic extracts.—When hydrogen peroxide is added to the concentrated reddish-brown toxic extract in the presence of alkali the colour is discharged and there is thrown down a white precipitate, largely amorphous but containing needle-shaped crystals, and insoluble in alcohol, alkali and water, but soluble in weak acid. A similar decolorisation and precipitation is produced when ozone is bubbled through an alkaline toxic extract. Ordinary air when passed through the toxic solution decolorises it very slowly.

Marked resemblance between the toxic extracts and urine.—Urine is highly toxic when injected into animals; the toxic substance in urine is soluble in water and in alcohol. When urine is evaporated down nearly to dryness a brownish material mixed with various salt crystals is obtained, which passes into solution when treated with alcohol. It resembles the concentrated alcoholic solutions of the endotoxins obtained from germs and other proteins both in colour and in smell. Like the toxic germ extracts, it contains a small quantity of a turmeric substance which passes into solution in acid acetone, ether, and chloroform, and moves to the positive pole on electro-dialysis. Like the toxic extracts from germs and other proteins, the concentrated urine solutions are decolorised by hydrogen peroxide and by ozone, producing a white precipitate containing some needle shaped crystals. The precipitate is insoluble in alkali, alcohol, or water. The crystals are quite insoluble in water. The above similarities are very striking and are almost sufficient to justify the speculation that the alcoholic extracts obtained by the detoxication process described under paragraph 2 represent the waste toxic products of the germs and other proteins, just as the urine represents the waste toxic products produced in the tissue metabolism of the living body.

4. *Value of the Endotoxic Substances in the Production of Immunity.*

J. A. Kolmer[17] and H. C. Wells[18] state that the endotoxins of germs, in contra-distinction to the highly organised exotoxins, such as diphtheria and tetanus toxin, do not induce the formation of antisubstances. Vaughan's experiments led him to believe that antisubstances were not formed against the toxic extracts obtained from germs by his process. Experiments with the toxic extracts obtained from the gonococcus by my process showed that this extract did not act as an antigen when used in the complement-fixation test for gonorrhœa. One would therefore conclude that the toxic extracts are not antigenic, and that no true antisubstances, such as agglutinins, precipitins, and lysins, are produced against them.

The fact that true antisubstances are produced against the exotoxins of diphtheria and tetanus, as well as against the snake venoms, seems to have engendered the belief that such antisubstances are produced against all germ poisons. It should remembered, however, that the "exotoxins" of diphtheria tetanus as well as the snake venoms are highly complex and highly organised protein substances, which are precipitable by alcohol and ammonium sulphate. Moreover, they are easily destroyed by heat. On the other hand, the endotoxic substances removed from germs by the detoxication process are not destroyed by prolonged boiling, and they are much simpler protein substances, not precipitable by alcohol or ammonium sulphate. If we bear these facts in mind it is not at all inconceivable that while the exotoxins and venoms can produce much immunity, the simpler endotoxins can produce none.

Some observers have been so greatly obsessed by the successful immunity produced against the diphtheria toxin as to maintain that the immunising power of a given germ inoculation is in direct ratio to its toxicity. They believe that any germ inoculation producing a highly toxic reaction produces more antisubstance than one wherein a less reaction results, due to low toxicity; but those who argue in this manner are obviously not well versed in these problems. They appear to forget or to be ignorant of the fact that there are other antisubstances besides antitoxins. A given bacillus or a given protein, as shown by Vaughan and myself, does not consist entirely of a mass of toxin. They consist in bulk of protein substances which are comparatively non-poisonous, and the toxin exists only in small amount. Are no antisubstances, such as agglutinins, precipitins, or lysins produced against the bulk of the foreign germ protein when injected into animals? The toxin advocates would appear to affirm that this is so, although experimental evidence is against them.

Agglutinins and lysins are well-known antisubstances produced against the bodies of germs, and I have never seen it stated anywhere that agglutinins or lysins are synonymous with antitoxins. Why, therefore, should they confuse immunity towards the exotoxins with immunity towards the bulk of the germ bodies? There is, perhaps, more reason in the argument that a given inoculation which produces a severe local and general reaction results in more immunity than one which produces only a mild effect. Yet again experience seems to disprove this belief. For example, if we inject tuberculin a very intense reaction may be produced, yet little or no perceptible formation of antisubstance occurs. On the other hand, it is well known that an extraordinary amount of antisubstance (lysin) is produced against sheep's red corpuscles when the latter are injected into a rabbit. The sheep's corpuscles are comparatively non-toxic to the rabbit and produce no great amount of reaction when injected. Quantities as great as 5 c.cm. of a semi-solid mass of the pure corpuscles can be injected intraperitoneally without killing the rabbit. The amount of hæmolytic antisubstance usually produced as a result of these inoculations is so great that the serum of the inoculated rabbit is often capable, even in a dilution of 1 to 20,000, of lysing the sheep red cells.

The above is an example of powerful immunity produced against a substance which might be classed as almost non-toxic. Tuberculin is a thousandfold more toxic, yet I doubt if it produces 1/1000th part of the immunity produced against the sheep corpuscles. In the face of such facts there is no reason why a detoxicated vaccine should not be a superior immunising agent to the corresponding toxic vaccine. Sheep's corpuscles are hundreds of times less toxic than even detoxicated germs. I believe therefore that one ought to aim at a still more perfect detoxication of vaccines. Indeed, it seems reasonable to suppose that if it were possible to inject 5 c.cm. of solid bacterial substance a much greater immunity to the germ would be produced than with a highly toxic inoculation of an almost invisible speck of, say, 1/100 mg. of tuberculin.

PART III.—THE COMPOUND NATURE OF PROTEIN ANTIGENS AND A PROBABLE BIOCHEMICAL EXPLANATION OF "COLLATERAL IMMUNITY" AND NON-SPECIFIC VACCINE THERAPY.

1. *Existence of Non-specific Vaccine Therapy and "Collateral" Immunity.*

It has been noticed by many observers that when a vaccine of a given germ is injected beneficial results are sometimes produced in diseases which are caused by an organism quite different from that injected. It is now well known, for example, that a curative effect is obtained in gonorrhœal rheumatism by injections of *B. typhosus* vaccine.

Sir Almroth Wright[23] states that "all of those who have had experience with vaccines will have seen cases where therapeutic effects lying quite outside the range of the particular vaccine employed, and therefore, as we thought, not quite creditable to science, have been obtained with vaccine therapy." Later[24] he says: "I confess to having shared the conviction that immunisation was always specific. . . . Presumptive evidence of collateral immunisation began gradually to filter in our minds. ...... Hints are conveyed to us that there may exist a useful sphere of application for collateral immunisation; and that such sphere may perhaps be found in cases where the infection is of very long standing. ...... We should discard the confident dogmatic belief that immunisation must be strictly specific. ...... We should proceed on the principle instead that the best vaccine to employ will always be the vaccine which gives on trial the best immunising response against the microbe we propose to combat."

We must go even further and face other facts, since it appears to have been proved that good results have been obtained by injections of non-bacterial proteins, such as milk, proteoses, and other protein split products (J. W. Jobling and W. Peterson,[19] C. Bull,[20] Dunkling and Jobling,[22] &c.). For the explanation of this non-specific protein therapy the theory of "protein shock" has been advanced. It is believed by some that the shock produced by the injection of a foreign protein stimulates the system to produce more antibodies towards any given germ which may be attacking it. Fr. Rolly and Meltzer,[27] H. Lüdke,[25] and numerous other workers found that a temperature of 104° to 107° F. artificially produced had a favourable influence on an established microbial infection. Heated animals were more resistant to injections of bacteria, and antibodies, such as agglutinins and bacteriolytic substances, were produced more abundantly in animals which were kept over heated. It may be that the heat (temperature) causes damage to the infecting organism; it may cause a more rapid formation of antisubstance or a more rapid and firm union between the antigen and the antibody produced against it. The beneficial effect produced by non-bacterial proteins, such as milk, &c., may therefore be due simply to the temperature reactions produced, since it is usually stated that for a good effect a temperature response is required. Although it may be admitted that injections of milk, &c., can occasionally have a favourable influence on the course of a bacterial infection, and although without doubt an intravenous inoculation of typhoid vaccine has often a curative action in gonorrhœal rheumatism, nevertheless it seems to me that such modes of treatment are a step backwards in the progress of vaccine therapy. It has been proved by thousands of experiments and by thousands of observers since the times of Pasteur and Pfeiffer that a specific antibody is produced against a definite germ by inoculation with the latter. We must never lose sight of this fact. Let us grant that "protein shock" and that temperature reactions have a beneficial action in the mechanism of antibody formation; but why shock the gonorrhœal subject with typhoid vaccine or milk injections when it is just as easy to produce the shock and temperature reaction with gonococcal vaccine, and at the same time produce specific antisubstances as well?

2. *A Possible Biochemical Explanation of Collateral Immunity and Non-specific Vaccine Therapy.*

It seems to me that an explanation of collateral or cross immunity can be found in the compound nature of antigens. An antigen as a general rule does not consist of one single protein substance. Professor Maurice Nicolle[26] has written as follows:—

> "Each cell and each humour represent in reality a '*mosaic of antigens*,' as first pointed out by Miss Raphael ...... Usually one of those antigens is dominant and generates an antibody equally dominant ...... Red blood corpuscles of the horse contain a dominant antigen and other secondary antigens which are also met with in the corpuscles of the ox and sheep (in which these secondary antigens are respectively the dominant ones)...... A famous antigen the Forssmann antigen, is to be found in varied cells and humours —viz., in the kidney and testicle of the guinea-pig, in the red blood corpuscles and serum of the sheep, in the kidney of the horse, and in the pneumococcus."

In the light of the biochemical researches which I have described in Parts 1 and 2 of this paper it is easy to understand how a given bacterium or protein consists of a "mosaic of antigens" since it is composed of a combination of several different substances or fractions, and when injected it will call forth the formation of a mosaic of antibodies towards these different fractions. I have shown that the gonococcus contains 75 per cent. of alkali-soluble substance. This alkali-soluble substance is, therefore, likely to be the dominant antigen in this case. An injection of gonococci will call forth antibodies to the alkali, acid, and alcohol-soluble fractions, but the dominant antibody is likely to be that directed against the alkali soluble part.

Although all germs contain alkali, acid, and alcohol-soluble fractions, &c., it must not be inferred that the alkali-soluble part of the gonococcus is identical, for example, with the alkali-soluble fraction of the tubercle bacillus. Recent researches by my brother, Dr. Robert Thomson, and myself have shown clearly that the alkali-soluble substance of various germs shows considerable differences, which can be demonstrated in the following manner. Let us take, for example, a solution of the alkali-soluble material from the gonococcus and the tubercle bacillus respectively. To each add a weak acid, such as N/1 HCl, until a precipitate is produced; centrifugalise and test the reaction of the supernatant fluids by means of suitable indicators.‡ In this way it is noticeable that the protein material is thrown out of solution at different points of acidity: thus some of the T.B. protein is precipitated at + 0·4 acid (Eyre's scale), whilst a second portion comes down at + 3·5 acid. With the gonococcus, on the other hand, the bulk of the protein comes down at + 3·4, + 3·5, and + 3·6 acid. Let us suppose for a moment that the proteins which are precipitated at the same hydrogen-ion concentration are similar, then it is conceivable that the tubercle bacillus and the gonococcus contain a small amount of a common protein or antigen—viz., that which precipitates at + 3·5 acid.

Again, it is found that when acid is added to milk the bulk of the casein comes down approximately at + 3·5 acid. It is, therefore, just possible that the casein is closely allied to the corresponding gonococcus protein which precipitates at the same point. If such similar proteins induce the formation of similar antibodies then the explanation of collateral immunity and the so-called "non-specific" protein therapy is simple and obvious. It appears to me that just as a crude oil is found to be a complex substance made up of several species of oil which may be separated by fractional distillation, so also the alkali-soluble and acid-soluble substances from proteins are complex, and made up of several species of proteins which may be separated by fractional precipitation.

---

‡ The reaction of protein fluids cannot be estimated by titration. Various indicators must be employed according to methods similar to those described by S. W. Cole.[21]

Our researches so far appear to substantiate this belief, and if it should eventually prove to be correct then there lies open before us the possibility of preparing or compounding an antigen calculated to produce antisubstances to many pathogenic species of germs at the same time.

BASAL METABOLISM AND ITS CLINICAL MEASUREMENT.

BY H. G. EARLE, M.A., M.B. CANTAB.,
PROFESSOR OF PHYSIOLOGY, UNIVERSITY OF HONG-KONG;
AND
J. STRICKLAND GOODALL, M.B., M.R.C.P. LOND., F.R.C.S., F.R.S. EDIN.,
SENIOR PHYSICIAN TO OUT-PATIENTS, NATIONAL HOSPITAL FOR DISEASES OF THE HEART, LONDON, AND LATE LECTURER ON PHYSIOLOGY, MIDDLESEX HOSPITAL, LONDON.

METABOLISM can be measured either in terms of heat production (direct calorimetry) or in terms of the respiratory exchange and quotient (indirect calorimetry). In the one case expensive apparatus, in the other much time and experience, have hitherto been necessary before reliable data are obtained, and although the clinical measurement of basal metabolism has received a good deal of attention in America its study in this country can scarcely be said to have begun. The development, however, of a portable apparatus by Benedict[1] whereby a direct measurement of oxygen absorption may be made with very little inconvenience to the patient and a great saving of time to the investigator has placed the whole subject on a different plane, and has made routine measurement a relatively simple matter.

The Benedict Apparatus.

This machine consists essentially of a closed circuit containing (1) a spirometer bell, (2) an electric fan, (3) jars for soda-lime and calcium chloride.

The patient breathes into and out of this circuit through a special mouthpiece, nasal respiration being cut out by means of a nose-clip. The spirometer is filled with atmospheric air and oxygen in the proportion of 1 : 2, and this mixture, together with the expired gases, is kept circulating by the fan through the soda-lime and so back to the patient. The spirometer moves in a water jacket, rhythmically with each respiration, and generally downwards as the oxygen is absorbed by the patient and the carbon dioxide is absorbed by the soda-lime. The spirometer is accurately counterpoised by means of a weight suspended from a freely moving pulley wheel, so that there is little or no resistance experienced by the patient in breathing through the apparatus. An index attached to the weight enables a direct reading to be taken of the oxygen absorption.

The calcium chloride jars are not necessary except when it is desired to measure the carbon dioxide output by noting the increase in weight of the soda-lime. As will be pointed out later, this observation is not a very reliable one, and in routine work it is better to dispense with it.

Objections, Precautions, and Improvements.

This apparatus, as well as the more elaborate "unit" apparatus which preceded it, has been somewhat severely criticised by Boothby and Sandford[2] in their recent book on the subject. Their objection can be summarised under the following headings, and though by no means valid can be used to indicate the precautions that must be taken in using this machine.

1. "*Constant checking for leaks.*" We have now used this apparatus constantly for three months, and find that with proper precautions the danger of leakage is not a serious one. If leakage occurs it is generally due to the face-, mouth-, or nose-piece used for connexion with the patient. It is for this reason that we prefer the mouthpiece and nose-clip to the mask. It is very difficult to adjust the mask to a nervous patient so as to avoid all leakage, and we abandoned it at the outset for this reason. The mouthpiece, on the other hand, is easily inserted and can be sterilised after each experiment. It is true that most people rather object to the nose-clip, and that normal breathing becomes somewhat altered at first in depth and frequency, but, as Benedict points out, this only alters the carbon dioxide output, and does not affect the oxygen absorption which this apparatus is specially designed to measure.[3]

2. "*The absorbing chemicals must be changed frequently.*" After all this only means one jar of granulated soda-lime, and we have found that many observations may be made without changing its contents. Moreover, much more attention must be paid to "chemicals" if a gas analysis apparatus is used. It is true that with the absorption of moisture as well as of carbon dioxide from the expired air, the soda-lime is apt to cake, with the result that there are increased resistance and diminished absorbing power. This condition is, however, soon recognised by the dyspnœa which it produces and can be remedied by the immediate substitution of a new jar in the place of the old. It may be suggested that the use of a calcium chloride jar by removing moisture will prevent "caking" of the soda-lime, but it is found that soda-lime absorbs CO_2 better if it is kept moist and that the risk of "caking" is the lesser of two evils. Further, it is very simple to test both the absorbing power of the soda-lime and the resistance of the apparatus, and this should be done at definite intervals so as to avoid inconvenience to the patient and inaccuracy of observations. It should also be quite easy to insert a small bottle of lime-water in the circuit between the soda-lime and the inspiratory tube, which would at once detect any deficient absorption of CO_2.

3. "*The chief objection to the apparatus is that it cannot be cleaned and the patient is exposed to the serious danger of infection.*" If this is true it is a very serious objection to the use of the apparatus, and if there really is a danger to the patient the apparatus should not be used, but we fail to see why the apparatus cannot be cleaned. The mouthpiece can be sterilised by boiling after each observation and the spirometer with its connecting tubes can be readily detached and cleansed. Further, the patient does not, as stated by Boothby and Sandford, inspire "the exhalations of previous patients," since the spirometer is emptied after each observation and filled with fresh air and oxygen, while any "impurities" in the connecting pipes can be "flushed out" by the electric fan. There is no more risk to the patient in breathing through this machine than in breathing the air of our cities, and there is less risk than that involved in using the public telephone. Recent exact observations made by Dobbin and published by Roth serve to confirm above statement.[4]

The further statement that "in the early there is the danger of the oxygen rich mixture on fire," a danger which is totally impossible later models, rather suggests that their criticism apparatus is based on prejudice rather than on experience. As already stated, it is desirable that the open-circuit method should be used as well, since fuller data can be obtained and with greater accuracy, but that is no reason why false criticism should be employed to discourage the use of a method which has a very real value.

4. Lastly it is stated "that error is introduced by failing either to start or to stop the experimental period at exactly the end of a normal respiration, a difficult thing to do with accuracy in the case of patients who breathe irregularly." This we consider is a real objection to the use of the present form of the apparatus, but we believe that it can be overcome by taking a graphic record on a kymograph, as apparently was done in the case of the larger "unit" apparatus introduced by Benedict.

We have therefore devised a kymographic attachment, using glazed paper and a pen, whereby a permanent record in ink of the whole test is obtained, as in the case of a polygraph. With the kymograph clock travelling at a known speed and a scale similar to that attached to the apparatus the oxygen absorption can be determined from the record at any point of the test. Further, valuable information is obtained of the character of the respirations in respect of depth, frequency, and regularity, and any hyperpnœa, such as might be caused by deficient carbon dioxide absorption is at once detected. An attachment like this can be made with very little additional cost, and by using glazed paper which can be kept rolled, the kymograph can be reduced in size and the inconvenience of smoking and varnishing avoided.

Method of Making Observation.

The patient is admitted overnight, or if this is not possible, is rested for one hour after arrival in the morning before the observation is made. No food is permitted after the previous evening—in other words, the observation is made after a 12-hours fast. The patient is gradually introduced to the test and its nature and purpose explained. The mouthpiece is first introduced, then the nose-clip, then both are used, in each case free breathing being permitted from the room atmosphere. Next the patient is connected with the apparatus, the valve being turned so that the ordinary atmosphere is still breathed. The fan is set going and the patient's eyes being closed the valve is now turned so as to connect with the spirometer and the excursions of the bell noted. As soon as regular breathing is established a reading is taken at the end of expiration and the 10-minute period started by means of a stop-watch. At the end of the period a similar reading is taken and the exact duration of the test noted—the valve is then turned back and the patient disconnected. In some cases it may be better to take two five-minute tests (e.g., with excitable patients), but in any case the readings taken can be checked and amplified by analysis of the record.

Calculation of the Metabolic Rate.

(1) The temperature of the spirometer and the barometric pressure are taken and the reading for the volume of oxygen used reduced to normal temperature and pressure. (2) The oxygen volume thus reduced is expressed in litres per hour, and assuming an average respiratory quotient of 0·82 the number of calories produced is determined from standard tables. (3) The surface area of the patient is obtained by means of the Du Bois curve from the height and weight and the metabolic rate is expressed as calories per hour per square metre. A reference to the standard figures for age and sex shows how much above or below normal is the rate of the patient under observation, and the basal metabolic rate (B.M.R.) is expressed as + or − per cent. of normal. Full details of the calculation, together with tables and standards, are published in a convenient form in the book by Boothby and Sandford, to which reference has already been made.

Using this method, we now have under investigation bout 50 cases of thyroid and heart disease, and we all hope later to publish results which will demonstrate the importance of these observations in the diagnosis, treatment, and prognosis of exophthalmic goitre, &c.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF
TUBERCULOUS SALPINGITIS.

By E. DRYBROUGH-SMITH, M.D., CH.B. EDIN.

THE following case is of sufficient interest, in view of its difficulty of diagnosis, to be recorded.

L. C., a girl of 20, was seen for the first time on Feb. 27th, 1918, when she complained of pain in the lower region of the abdomen and vomiting after meals. Her mother explained that at times patient had fits in which she tore her hair and bit herself. The illness started five years ago with pain in the abdomen and vomiting, and had continued more or less ever since, preventing her from walking and doing any kind of work. She had once been sent to hospital for operation, but was discharged without operation because, in a fit, she had bitten a nurse. She had one brother who was mentally deficient, and there was a history of tuberculosis in her father's family.

On examination patient was rather pale in general appearance, but well nourished; the abdominal pain was worse before menstruation, which was regular; the bowels acted normally. She could not stand upright, but with the body flexed and with the aid of a stick she managed to cross the room. The heart, lungs, and urine revealed no abnormalities; there were no enlarged superficial glands. Temperature was 99·4° F. and pulse 84. The abdomen moved freely, and in general appearance showed nothing abnormal. On pressure there was some tenderness over the appendicular region; on deep pressure an indefinite soft mass could be felt. Vaginal examination revealed slight tenderness in the region of the right tube; the uterus was normal in size and position and freely mobile. Nothing further was found on rectal examination. Considering the long history of pain and vomiting, the slight fever and mass felt in the abdomen, it was thought these might be due to adhesions connected with chronic appendicitis.

On March 13th, 1918, I opened the abdomen through the sheath of the right rectus. Adhesions were seen spread over the cæcum and termination of the ileum; there was no free fluid in the abdomen; the right Fallopian tube was thickened, its surface being rough, and scattered over its peritoneum were many small greyish-white tubercles; the ovary looked normal; the remaining organs and peritoneum of the pelvis appeared healthy. The appendix was abnormally thick and felt hard. On the cæcum and terminal portion of the ileum were seen a few tubercles; otherwise the intestines appeared free from disease. The right tube and ovary and the appendix were removed and the abdomen closed. The patient made a good recovery.

The pathologist's report stated: "This is a tuberculous lesion of the Fallopian tube and appendix. The tube shows adhesions of the plicæ, leucocytic infiltration, giant-cell systems, and small caseous foci. The appendix also shows masses of epithelial cells and giant cells in the lymphoid tissue; the mucous membrane appears to be destroyed, but curiously there are no tubercles on the peritoneal surface in the section. The ovary is not involved."

The patient remained well for a year; she could stand erect and walk several miles. An attack of influenza was followed by pulmonary tuberculosis from which she died in March, 1920.

Remarks.

In this case a definite diagnosis before operation seemed impossible. The hysterical attacks are of interest in showing the possibility of such attacks overshadowing the more serious condition. The various ways in which abdominal tuberculosis may reveal itself is very striking. In December, 1916, I operated for strangulated hernia on a stout woman of 58, whose intestine was covered with miliary tubercles; in spite of this fact she appeared to be in good health before the accident to her hernia. In 1917 I sent a girl of 21 to Dr. Edwin J. Toye, of Bideford; this patient had a large rounded mass growing up out of the pelvis, reaching nearly to the umbilicus, and Dr. Toye informed me that on opening the abdomen the appearance of this mass was carcinomatous. The abdomen was closed and the patient treated for a time in the fresh air; the mass has disappeared and the patient is living and apparently in good health.

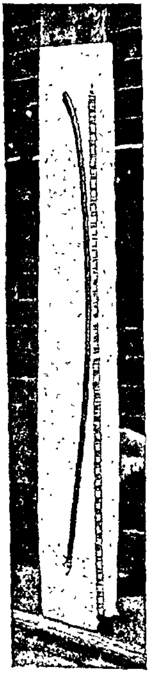
Shebbear, N. Devon.

A CASE OF
TRANSFIXION BY STEEL ROD.

BY NORMAN C. LAKE, M.D., M.S., D.SC. LOND., F.R.C.S. ENG.,
ASSISTANT SURGEON, CHARING CROSS HOSPITAL.

THE following case is reported primarily because it is in many aspects unique, and secondarily in view of the discrepant accounts which unfortunately found their way into the lay press.

The patient, aged 24, was working at the bottom of a lift shaft on March 30th, when a steel rod, ¼ in. in diameter and 54 ft. long, weighing 34¼ lb., fell vertically from a height of 50 feet. He was four or five steps up a ladder at the time, and was bending a little forward, and the rod entered his body just behind the left shoulder. After traversing his body it made its exit at a point on the inner aspect of the right knee, and, when some 9 ft. of the rod had passed through and embedded itself in the ground below, its career was arrested. While thus transfixed the man fell sideways with the rod until its upper end rested against the side of the lift shaft. As the lower end was firmly embedded in the ground bending occurred at the point of exit from the body. At this stage between 3 and 4 ft. of the rod traversed the man's body, while about 40 ft. projected above. He supported himself by clutching at some staging, while his fellow workmen, in order to extricate him from this position, divided the rod with a hack saw about 2 in. above and below the points of entrance and exit respectively. He was then transferred to hospital still "splinted" by the remainder of the rod.



Reproduction of photograph of steel rod after removal, showing curvature resulting from its fall.

Condition on Admission to Hospital.

Upon admission he was suffering from considerable shock, recovery from which was, however, rapid. The entry wound was situated behind the neck of the left scapula and was surrounded by an area of surgical emphysema. The wound of exit was immediately on the inner side of the right knee-joint, also surrounded by an area of surgical emphysema, and, of course, with two inches of the rod projecting. Except that a small portion of the rod could be felt by deep palpation below the right gluteus maximus muscle, there was little to indicate the course which it had taken. Examination of the chest revealed the presence of a left hæmo-pneumothorax. The abdomen was in a condition of absolute rigidity all over, rectal examination was negative, and the urine was normal. There were no signs of injury to nerves or to the spinal cord.

Further examination showed that the rod was very firmly embedded and that considerable force would be required for its removal. In view of the fact that so little of the rod was available externally, it was thought advisable to tap a screw thread on the lower end to enable sufficient tractive force to be applied for its removal. The patient was therefore anæsthetised by Dr. S. F. Fouracre and transferred to the X ray department, where a rapid screening showed that the rod took a somewhat curved course, convex to the right, but luckily with no angulation. It was impossible to screen in two directions owing to the fact that the man was effectually splinted by the rod. Since there was absolute abdominal rigidity, and as it was still impossible to say accurately what the condition of affairs might be inside the abdomen, a laparotomy was performed by an extensive mid-line incision. This was deemed advisable, not only on account of the rigidity, but also because it was very necessary to be prepared to deal with any eventualities which might occur during the extraction of the rod. Even with the abdomen open it was difficult to determine the exact course which it had taken.

Course of the Rod.—As far as could be made out after passing through the posterior aspect of the left lung, it penetrated very obliquely through the bodies of three or four vertebræ in the lower dorsal and upper lumbar regions, and as there was no leakage into the peritoneum from any viscus, it was obvious that the rigidity was due to irritation of the nerve roots in this situation. Leaving the vertebral column in the right lumbar region the rod could be felt below the pole of the right kidney and just behind the inferior vena cava. At this point it passed for about half an inch into the peritoneal cavity without causing any damage, and again became extraperitoneal by penetrating the psoas muscle. It appeared to have the abdominal cavity by drilling a hole through the brim of the pelvis behind the acetabulum, and having passed down the back of the thigh, guttered the internal condyle of the right femur before leaving the body.

The engineer now tapped a light screw thread on the lower end of the rod, the stock being used as a convenient handle for traction. The upper end of the rod having been sterilised, traction was applied in the direction of the curvature on the rod, which was thus slowly removed while a close watch was kept for internal hæmorrhage, &c. The shock of removal was very great but yielded to appropriate treatment, and as there was no excessive bleeding the abdomen was closed without drainage, while small tubes were placed in the entrance and exit wounds.

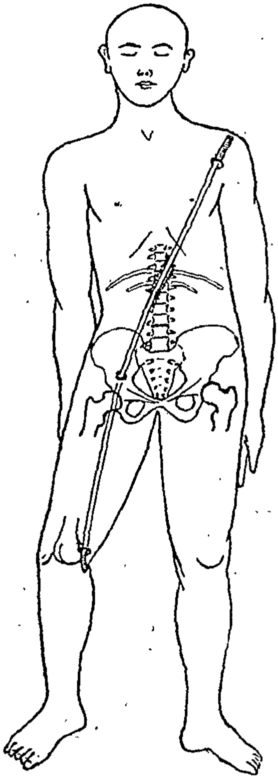


Diagram showing course taken by the rod through the man's body.

Sequel.—The subsequent history is rather uneventful; the temperature remaining down and there being no signs of extensive infection. The abdominal rigidity did not clear up until the fourth day, and the hæmo-pneumothorax is still present although diminishing. Further examination of the patient since the operation has revealed no signs of any extensive nerve injury nor damage to other important structures.

The portion of rod removed is 3 ft. 6½ in. long; there was nearly 2 in. exposed at either end, actually in the body being 3 ft. 3 in. in weighing 2 lb. 6 oz. The curvature of the occurred while it was in the body, and the stated to have been cut square and not in

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF TROPICAL DISEASES AND PARASITOLOGY.

LABORATORY DIAGNOSIS OF MALARIA.

A MEETING of this section of the Royal Society of Medicine was held on April 4th, Sir LEONARD ROGERS, the President, occupying the chair, when Dr. W. BROUGHTON-ALCOCK read a paper entitled

Laboratory Observations on Pensioners who Contracted Malaria in the Late War.

At the outset he emphasised the importance of collaboration between laboratory workers and clinicians and the need for research, particularly in the diagnosis of latent malaria in Europeans who had returned from tropical and subtropical endemic areas. To give an idea of the number of possible applications for a pension on account of malaria, and there were no fewer than 52,480 fresh claimants in Great Britain and Ireland as lately as last year, figures were quoted giving the number of admissions to hospital or malaria during the war in Mesopotamia (18,626), Salonika (161,559), Egypt (40,144) in 1916, 1917, and 1918, and East Africa (78,242) in 1917 and 1918, providing the formidable total of close on 300,000! The highest admission rates for malaria in one year were in Salonika 71,413 and in East Africa 58,236, both in 1917. His observations were based on recent work carried out at the Pensions Central Laboratory between October, 1919, and February, 1921, and were necessarily directed to the diagnosis of malaria among those who had returned from tropical and subtropical regions, including cases which could be regarded as having attained radical cure by quinine, or as suffering from latent malaria, or exhibiting recurrent attacks. A number of demobilised soldiers from the East were still claiming pensions for malaria or its results, but many showed no clinical signs of the disease, and no parasites could be found in their blood films. It was doubtful whether their condition was due to malaria or a disease simulating it. Hence arose the question of the reliability of the large mononuclear count as a guide to malarial infection, particularly in latent cases.

There was much difference of opinion as to what constituted an increase in the relative percentage of the large mononuclears, few authors stating the minimum figure. The tabulated results of the work done and observations made between October, 1919, and February, 1921, which were distributed at the meeting, showed that a total of 28,270 cases had been examined, coming from no fewer than 22 recorded areas of inspection, chiefly in the East, but including also East, West, and South Africa, England, France, and Germany. Nearly 12,000 alone of this total came from the Balkans and about 3000 from India. The laboratory work included the close search for parasites and pigment over a period of 15 minutes through both thick and thin blood films from each case, and the total and differential count of leucocytes, with particular reference to the large mononuclears. Longer than 15 minutes was devoted to the search for parasites when a large mononucleosis was found, or if the claimant showed enlargement of the spleen. The use of the thin film carefully spread was now advocated as yielding better results than the thick, and in the differential enumeration attention was directed to counting along each edge of the film and over the central portion as well. The term large mononuclear included the synonyms endothelial leucocyte, macrophage, hyaline and transitional cell, and was carefully separated in differential counting from the large lymphocyte. Out of the 28,270 cases, 777 had shown positive findings of malarial parasites, 759 being *P. vivax*, 14 *P. falciparum*, and 4 *P. malariæ*. Particulars were given under the 22 recorded areas of the number of cases found positive, including the type of parasite, on one occasion only and more than once; also of the positive findings and the period after return of the pensioner to residence in England. It was hoped to ascertain from these particulars whether cases coming from one area—e.g., Palestine—became free from parasites under quinine treatment at home earlier or later than those from another area—e.g., Salonika—but so far this had not been fully worked out. The question seemed one of considerable interest. A further table under separate headings gave the months between October, 1919, and February, 1921, and the number of blood examinations made in the central laboratory in each month, together with the total cases found positive on one occasion and more than once for each month, including the type of parasite; also the monthly number of cases found positive; it showed the tendency to clear up after 8 to 12 months' out-patient treatment. A table was also exhibited giving, out of a total of 801 most carefully detailed examinations, the number of cases presenting enlargement of the spleen (127), normal spleen (674), enlargement of the liver (52), normal liver (749), presence of anæmia (94), absence of anæmia (707), abnormal condition of heart—e.g., tachycardia, hæmic murmur, dilatation and disordered action (22), normal heart (779). The correlationship of the normal or abnormal clinical conditions of the spleen, liver, blood, and heart respectively were also included in the tabulation of the cases, together with the absence or presence of malarial parasites and the relative increase of large mononuclears (10 per cent. and over, as well as 15 per cent. and over); of lymphocytes (31 per cent. and over); and of the two types of cells combined. A second table including these 801 cases, and 18 others more recently infected, gave the classified relationship between the time from the date of the first attack of malaria (within six months, one, two, three years or over) and the recorded clinical observations with reference to the condition of the spleen, liver, and heart, and the absence or presence of anæmia, and the corresponding blood findings as to the relative increase or not of the large mononuclears, lymphocytes, and the absence or presence of malarial parasites. The percentage of cases showing the presence of malarial parasites within the various periods following the first attack of malaria was as follows:—

Within 6 months after the first attack ...	33·3 per cent.
,, 1 year ,, ,, ...	8·3 ,,
,, 2 years ,, ,, ...	4·5 ,,
,, 3 ,, ,, ,, ...	2·7 ,,

The clinical features similarly showed a marked decrease with the lapse of time and return to England, and the two gave support to the view that under rational quinine treatment at home the bulk of malarial cases cleared up in 8 to 12 months.

The conclusion to be drawn from these tables was that a relative increase of the large mononuclears was not constant in latent malaria, even in the presence of an enlarged spleen when the diagnosis of latent malaria was obvious. A further table provided details of other cases undergoing treatment which showed under or over 10 per cent., as well as under or over 15 per cent., of large mononuclears:—

(1) When no parasite was found and the duration of the period, 1 to 7 months, prior to finding of the parasite (71 cases).

Large	mononuclears	over 10	per cent. in	28	per cent.	of cases.
,,	,,	under 10	,,	72	,,	,,
,,	,,	over 15	,,	12·5	,,	,,
,,	,,	under 15	,,	87·5	,,	,,

(2) When the parasite was found (200 cases).

Large	mononuclears	over 10	per cent. in	59	per cent.	of cases.
,,	,,	under 10	,,	41	,,	,,
,,	,,	over 15	,,	32	,,	,,
,,	,,	under 15	,,	68	,,	,,

(3) In subsequently negative cases, from 1 to 11 months after disappearance of parasite (121 cases).

Large	mononuclears	over 10	per cent. in	36	per cent.	of cases.
,,	,,	under 10	,,	64	,,	,,
,,	,,	over 15	,,	18	,,	,,
,,	,,	under 15	,,	82	,,	,,

(4) In cases more than once positive for malarial parasites after 1 to 12 months (53 cases).

Large mononuclears	over 10 per cent.	in 49	per cent.	of cases.
,, ,,	under 10 ,,	,, 51	,,	,,
,, ,,	over 15 ,,	,, 27	,,	,,
,, ,,	under 15 ,,	,, 73	,,	,,

But no reliance could be placed on the figures in table (4) *owing to the uncertainty of the technique* applied—e.g., the use of the first drop of blood from the ear—now known to be fallacious; also the ill-defined relationship of the time of the blood film and positive findings to the period of the paroxysms; and the possible influence of quinine treatment in the leucocytolytic action, and consequent exaggeration of polymorphonuclear leucopenia, while leaving the mononuclears intact or increasing them—all factors responsible for erroneous conclusions if based on results of the differential counting of such blood films.

The conflict of views as to the relative percentages of large mononuclears in malaria and post-malarial conditions and what constituted an increase was dwelt upon as matter for discussion and clear definition, and the solution of such wide divergence of opinion was claimed to be provided by Dr. Lucey's work, showing particularly the fallacies attaching to the use of the first drop of blood taken from the ear. In the normal person the large mononuclear percentage showed a wide range, a figure as high as 10 per cent. being excessively rare. In his observations on malarial pensioners he had taken the low basis of 10 as well as 15 per cent. In taking the lower figure as a basis of mononucleosis he was influenced by the possibility of finding a constant for the large mononuclears in latent malaria, which might prove of value in the diagnosis, and so benefit the assessment of pensioners and give them opportunity for treatment. Response, too, varied in individuals, and a rise from a low figure to 10 in one person possibly signified as much as a response to 15 per cent. in another. Moreover, under the more favourable conditions associated with the soldier's return to a milder climate and better living at home, it was conceivable that in latent malaria in England the large mononucleosis was less developed and accompanied the disappearance of the parasite. Stephens and Christophers, from the examination of a large number of Europeans living in the tropics, regarded a mononuclear percentage of over 15 as evidence, now generally accepted for the tropics, of recent or existing malarial infection. This increase was most marked in the apyretic period, but was most often absent during the fever. Dr. Rieux's study, at the Val-de-Grâce Hospital, Paris, of the leucocytic formula in old malaria cases showed that the "monocytes," lymphocytes, and eosinophils returned to the normal with subsidence of the fever and disappearance of parasites from the blood; only the neutrophil figure was definitely diminished for several months, a year or even longer. Respecting the presence of parasites after the patients' return home, French authorities found that they rarely persisted after 8 to 12 months, and with this period experience in England generally agreed under the influence of rational quinine treatment. Mononucleosis was reported to last for some time after malaria in the tropics, but this was not found to be the case in observations on latent malaria at home, where, following quinine treatment and the disappearance of parasites, the relative increase in the number of large mononuclears did not persist beyond a few days. An explanation was needed to account for the differences in the duration of mononucleosis in the tropics compared with its short period after a malarial attack at home.

In cases of latent malaria at home Dr. Broughton-Alcock considered that the diagnosis and treatment should not be influenced by the absence of a relative increase of large mononuclears, when the clinical history and physical signs could be depended on. Moreover, though clinical evidence might be strengthened by a relative mononucleosis, often present between two attacks in the apyretic period, yet such increase could not be regarded as depending on or invariably associated with enlargement of the spleen, so important a clinical sign in latent malaria. Reference was made to the value to be derived from the estimation of quinine in the urine for the purpose of watching its *elimination during treatment and in the detection of* malingering.

Dr. H. C. LUCEY followed with a paper containing observations bearing on the reliability of the

Large Mononuclear Leucocyte Count as an Aid to the Diagnosis of Malaria.

The importance attaching to the diagnosis of latent malaria and conditions simulating malaria was one which could not be under-estimated in dealing with the large number of demobilised soldiers returned from the East and claiming pensions on account of reputed malarial relapses or the effects of past attacks. In the absence of clinical signs and with failure to find malarial parasites, reliance had been placed on the large mononuclear leucocyte count as an aid to correct diagnosis, the assumption being that a percentage of 12 large mononuclears, or over, should be regarded as evidence of malaria. Granted that an increase in the large mononuclears was an indication of malaria, he asked how long after an attack this increase lasted? In the event of a raised large mononuclear count, was the patient still to be regarded as suffering from malaria? What were the definition and significance of latent malaria and the blood condition associated with it? The further question as to whether the large mononuclears were ever increased in the normal person was dealt with at some length in his recorded observations. These went far to explain the fallacies which might arise by taking the blood from the ear for the differential count, particularly in the use of the first drop of blood. The results of his investigations showed that this procedure was apt to be followed by a quite erroneous picture of the state of the blood in the general circulation, notably in the case of the large mononuclears. The fallacies referred to were illustrated by a series of tables representing a large number of counts. These he had made from films taken under varying technique, from the first, second, and third drops of blood from both lobe and border of the ear, the finger pulp, below the nail-bed of the finger, and from a vein. A number of control tests were carried out on normal individuals as well as on malarial pensioners. He showed that it was possible for the first drop taken from the ear of a normal person to yield a percentage of large mononuclears as high as 30 to 40, whereas the succeeding drops, especially of the third, from the ear, and in the case of the finger the first drop of blood would yield only a normal percentage of 5 to 8 large mononuclears. This fallacious increase of large mononuclears he had found also to hold good with malarial patients when films were examined from the first drop from the ear, in which the percentage was also about 30, while succeeding drops yielded a picture of the true mononucleosis of 15–20 per cent. or more. Tables of further observations showed that when the ear was manipulated by firm handling or the application of friction previous to puncture, films from the first drop of blood gave no large mononuclear rise. Similarly, too, any measure tending to increase the rate of circulation, such as application of heat or ether to the ear, or muscular exercise, failed to produce any rise above the normal. Conversely, after ice had been applied to the ear as a consequence of the retarding of the blood flow through the capillaries, the false mononuclear rise shown by the first drop of blood previous to the application of the ice remained unaffected in the second drop.

He explained the error occasionally attaching to the use of the first drop, and to the second drop if the first was small, by the known fact that the circulation in the ear was sometimes slower than in the rest of the body. Consequently the large mononuclears tended to adhere to the walls of the blood capillaries or to collect perhaps in the lymph spaces. They therefore appeared in the first drop of blood shed in larger numbers than really existed in the general circulation, and in parts—e.g., the finger—where the circulation was brisk. For that reason the second and, preferably, the third drops from the ear gave the truer picture of the relative numbers of leucocytes in the blood stream. His observations showed that this stagnation and accumulation were overcome either by allowing the earliest drops to escape after puncture of the ear, or by the previous application of exercises, friction, ether, &c., to increase the rate of blood flow through the ear, and so yield a reliable film. He claimed that the conflicting opinions expressed as to the relative number of large mononuclears both in malaria and other conditions, as well as in the normal state, could largely be explained by the counts derived from films taken from the ear, particularly if the first drop of blood had been used. On the other hand, blood taken from the finger, whether friction was applied or not and whichever drop was used, was always trustworthy and therefore to be preferred for both total and percental leucocyte counts. Dr. Lucey concluded by stating his opinion that "a reliable large mononuclear count, done during or within a few days after a questionable attack of malaria is an aid to diagnosis if the count is high. If it is low, it is of no help one way or the other."

Discussion.

Sir RONALD ROSS spoke in high appreciation of the authors' work at the Ministry of Pensions Laboratory. He regarded mononucleosis as of doubtful value in the recognition of past malaria and not to be compared in importance with the finding of parasites or pigment particles, although an increase of the total mononuclear cells was regarded as associated with both sleeping sickness and malaria, but not in his own experience.

Professor WARRINGTON YORKE confirmed Dr. Lucey's observations as to the erroneous increase of large mononuclears shown by the first drop of blood from the ear. He questioned the validity of the results obtained by two different observers, not only in counting two separate drops taken from the same person at the same time, but also in their examination of one film. It was very doubtful whether the two independent counts would be in agreement. Such lack of conformity might show a divergence of as much as 10 or 12 per cent., and be due to the varying distribution of mononuclears and polymorphs in the same film, and to one count being made in the centre, the other along the edges, the most reliable part of the film. Had, therefore, differential leucocyte counts any value at all? He personally regarded them as useless in the recognition of malaria, and the only reliable blood diagnosis was the finding of parasites, after suspending the use of quinine in the case of pensioners under treatment. He asked for a definition of latent malaria, and whether enlarged spleen taken as a sign of latent malaria implied the persistence of parasites in the body.

Professor W. J. R. SIMPSON paid tribute to the excellent work being done by Dr. Broughton-Alcock and his staff at the Pensions Central Laboratory, and was of opinion that their results would prove of the greatest value in the recognition of malaria among pensioners.

Dr. A. POWELL, from his experience in Bombay, attached considerable value to the leucocyte count, particularly under the correct technique as detailed by Dr. Lucey, in the differential diagnosis of malaria, seven-day fever, and tuberculosis. He found it difficult to provide an answer to Dr. Broughton-Alcock's question as to the value to be attached to the leucocyte count in malarial cases at home. The conditions varied much in tropical countries compared with those at home, both as to the reliability of patients' statements and as to the circumstances under which blood examinations were made. The personal equation of the counter had to be taken into consideration, and it was therefore of importance that the counts if possible should be made by one observer rather than by several.

Dr. J. GORDON THOMSON referred to the time of blood examination during the malarial attack as portant. Bailey's observations, that during the roxysm there was a leucopenia, but in the interval ween the paroxysms a leucocytosis occurred due to increase of the large mononuclears, had been con- ed by David Thomson.

Dr. H. J. B. FRY quoted from observations which had been made on 1083 cases with history of malaria. In 27, or 2·5 per cent., *P. vivax* had been found; the large mononuclear count in 10 of these was above 10 per cent. and in the remaining 17 below 10 per cent. He had not found that the mononuclear count was related either to the period of the fever, the condition of the spleen, the anæmia, or cardiac insufficiency of the malarial cases.

Dr. BASIL PRICE spoke of the diversity of views which had been expressed as to the value of the large mononuclear count, and of the importance of the fallacies as exposed by Dr. Lucey, whose observations, he felt sure, would result in a considerable revision of opinions hitherto held and a revival of interest as to the significance of the large mononuclear cells in the diagnosis of malaria.

Professor LEONARD DUDGEON quoted the results of observations carried out on malarial carriers among the British Salonika Force in the Struma Valley during the winter of 1916–1917:—

1. Total number of cases* examined, 2836. Parasites present in 724.
No parasites present.
Pigmented leucocytes found in 111 cases. Number of large hyaline cells over 15 per cent in 312.

* Hospital admissions from all causes.

2. Total number of cases examined, 1053. Positive history of malaria, 1010.
Two relapses or more in 471 cases. Malaria parasites present in 219 cases.
No parasites found, but large hyalines over 15 per cent. in 399 cases.

At St. Thomas's Hospital during 1919 and 1920 there was no case in the records of the pathological department showing 15 per cent. or more of large hyaline cells, apart from malaria, and only 1 per cent. of cases with a large hyaline cell count as high as 10 per cent. He never took the first drop of blood for film examination, and recalled, as a student, that Professor C. S. Sherrington when lecturing on "The Blood" had warned them to avoid the use of the first drop owing to the fallacious increase in the large mononuclears contained in it.

Dr. A. CASTELLANI regarded mononucleosis of value as a subsidiary aid to the recognition of malaria, and from his experience in Ceylon he had found the large mononuclear increase to persist for a considerable period after an attack, but in greatly varying degree; he was unable to state to what extent this increase and variation prevailed at home as compared with the tropics.

Dr. J. B. CHRISTOPHERSON inquired whether any observations had been made as to the effect of other drugs than quinine on the leucocyte and large mononuclear counts, and what those drugs were.

The PRESIDENT asked how long mononucleosis lasted after malaria. He had found a marked increase of the large mononuclears in active malaria cases due to the benign tertian parasite, especially between the paroxysms, and, as shown by Stephens and Christophers, that increase was present after recent attacks.

Dr. ERNEST BLACK and Lieutenant-Colonel EDMUND WILKINSON, I.M.S., also spoke.

Reply to the Discussion.

Dr. BROUGHTON-ALCOCK, in his reply, stated that he still felt, even after the discussion, the need for the opinion of others as to the duration and degree of the large mononuclear increase among malarial pensioners at home. The use of the term latent malaria was applied to cases sent for quinine treatment, and among them enlargement of the spleen provided the most important clinical evidence of malaria. He quoted an observation made by Craig, in America, in which, out of 1267 cases showing malarial parasites 21 per cent. were cases of latent malaria. The average case usually cleared up at home and did not suffer further after a period of about 12 months. It was very difficult to apply the stoppage of quinine treatment to pensioners in the hope of finding parasites; similarly, as to the time of blood examination, films had to be taken when possible, and no definite time could be fixed. He vainly sought for an answer as to whether the large mononucleosis found in the tropics applied to malarial cases at home, and if the explanation lay in the difference between the two climatic conditions. From his experience in England the large mononuclears, if increased, showed an intermittent rise for a period of less than seven days following a malarial attack, and he gathered that in the tropics this period was considerably extended. Was this ever found to be the case in this country? He asked for a clear definition of the hyaline cells and large mononuclears, and pointed out that Professor Dudgeon's observations in the Balkans had been carried out on persons living under active service conditions in an endemic area and exposed comparatively recently to malarial infection, a state not comparable with that prevailing among pensioners at home. In reply to Colonel Wilkinson's question as to whether any other laboratory sign than mononucleosis was to be found among malarial pensioners, he could say that no other unquestionable laboratory diagnosis existed than the finding of malarial parasites or pigment, as his tables showed. If an increase of large mononuclears was found on the edge of the film it was important to search thoroughly for parasites. He could give Dr. Christopherson no particulars as to the influence of other drugs than quinine on the leucocyte count, but quinine had a leucocytolytic action in causing leucopenia, though leaving the large mononuclears unaffected.

SECTION OF SURGERY: SUBSECTION OF PROCTOLOGY.

PRURITUS ANI.

A MEETING of this subsection of the Royal Society of Medicine was held on April 13th, Mr. A. E. MILES, the President, being in the chair, when Mr. J. P. LOCKHART-MUMMERY opened a discussion on this subject.

Pruritus ani, he said, was a peculiar condition in that it had only one symptom—namely, itching. It had no established pathology, and we were still in the dark as to its cause or the best method of treating it. It was by no means the trivial complaint that its name would imply. The irritation was often so intense as to drive the patient to the verge of madness. The thickening of the skin, the rugæ and eczema, fissures, and other abnormal conditions of the skin around the anal orifice frequently associated with pruritus ani were secondary results of scratching, and beyond the fact that they tended to accentuate the itching and interfere with treatment had no causal relationship to it.

Certain definite types of pruritus ani were to be distinguished: (1) those due to some general condition, such as glycosuria, &c.; (2) those due to some parasite, such as worms, pediculi, &c.; (3) pruritus obviously secondary to some lesion of the anal region, such as fissure, prolapsed pile, &c.; (4) pruritus of old standing where no local lesion can be discovered; (5) paroxysmal pruritus. A local cause for the itching was present in a great majority of cases, and the first essential was to make a thorough search for this cause. Where a definite cause for the pruritus was discovered it was generally one which produced moisture of the parts, more particularly of a septic character, such as fissure or fistula, a polypus of the rectum, or a prolapsed pile. In the case of itching of recent origin removal of the cause was followed by prompt and permanent relief. The difficult cases were those in which no local cause could be discovered, and more particularly the paroxysmal cases, where it was unusual to find any local lesion. With a history dating back for more than two years removal of any local lesion present seldom stopped the itching. It seemed reasonable to conclude that under the circumstances definite changes took place in the skin or in the nerve-endings in the skin. He believed these changes to be of the nature of a fibrosis in the deeper layers involving more especially the end-plates in the dermis and caused by the constant scratching and rubbing. In fact, in these old-standing and severe cases of pruritus an actual disease of the nerve-endings in the skin existed, as was first realised by the late Sir Charles Ball. In 1912 Dr. Dwight Murray put forward the theory that pruritus ani was due to a chronic streptococcic infection of the skin of the anal region. He pointed out that careful investigation by bacteriological methods had proved the presence of *Strept. fæcalis* infection in the vast majority of cases. Mr. Lockhart-Mummery considered that the truth of this theory was now established. In support of it was the fact that a septic lesion was the common starting-point of pruritus. We also know that chronic septic foci of the skin in other parts of the body are frequently accompanied by intense irritation. It is possible that the disease of the nerve-endings in these old-standing cases of pruritus ani is due to this infection rather than to any immediate result of the scratching. Investigation was necessary, but it was difficult to obtain portions of skin for histological purposes, and histological investigation of nerve-endings was itself difficult.

General treatment, such as dieting, non-smoking, total abstinence, &c., Mr. Lockhart-Mummery did not believe in. We ought to try to cure the condition and not to make the patient a slave to his anal region. Rigid attention to local cleanliness and dryness was very important. Lotions and powders were better than ointments. Any local cause, such as fissure, ulcer, pile, hypertrophied papilla, &c., should be removed, and it was often advisable to investigate the anal region under an anæsthetic. Dr. Dwight Murray had suggested the use of a vaccine, but it did not seem reasonable to him, Mr. Lockhart-Mummery said, to treat a septic infection of the skin by vaccine. Antiseptics, such as alcoholic solution of iodine, might be used, either painted on or applied by ionisation. Zinc ionisation or the application of nitrate of silver 30–60 g. to the ounce had given good results. X rays applied to the skin through suitable screens had cured about 20 per cent. of his bad cases. Two or three applications were usually sufficient. It was unwise to persist if marked improvement did not follow two applications.

Operative treatment remained for the cases not remedied by other means. No operation which did not destroy the diseased nerve end-plates in the dermis would remedy old-standing cases. Twenty years ago such cases were treated by excision of the anal skin or the drastic application of the actual cautery. The results were bad owing to the scarring. No such drastic measures were necessary. Sir Charles Ball described an operation for the division of the cutaneous nerves passing to the skin in the anal region. Mr. Lockhart-Mummery had performed it at St. Mark's Hospital since 1905 with excellent results. Other surgeons had condemned it. It was essential that the whole of the irritable area of skin should be rendered completely anæsthetic. The day after the operation the patient should be quite unable to feel the prick of a needle anywhere within the flaps or at the anal orifice. It was easy to miss some of the nerves, but unless they were all divided success could not be expected. In raising the flaps the skin should be undercut well above the level of the internal sphincter. This operation gave immediate relief and left no disability. Normal sensation returned completely within six weeks, generally within four. In the vast majority of cases the cure was permanent. Mr. Lockhart-Mummery had performed this operation in 59 cases; there was a slight recurrence of itching in 7 cases. Four of these were easily cured by simple application, and in 3 cases the operation was repeated with complete success. There was no serious complication, and no patient was kept in hospital or in a nursing home for more than six weeks, the average time being under three weeks. In all these cases normal sensation was restored, and there was no disability.

Discussion.

Dr. ARTHUR WHITFIELD said that, in his experience, pruritus ani was frequently caused by the oxyuris, the presence of which was seldom suspected, and he instanced the case of a lady who consulted him. He from the ear gave the truer picture of the relative numbers of leucocytes in the blood stream. His observations showed that this stagnation and accumulation were overcome either by allowing the earliest drops to escape after puncture of the ear, or by the previous application of exercises, friction, ether, &c., to increase the rate of blood flow through the ear, and so yield a reliable film. He claimed that the conflicting opinions expressed as to the relative number of large mononuclears both in malaria and other conditions, as well as in the normal state, could largely be explained by the counts derived from films taken from the ear, particularly if the first drop of blood had been used. On the other hand, blood taken from the finger, whether friction was applied or not and whichever drop was used, was always trustworthy and therefore to be preferred for both total and percental leucocyte counts. Dr. Lucey concluded by stating his opinion that "a reliable large mononuclear count, done during or within a few days after a questionable attack of malaria is an aid to diagnosis if the count is high. If it is low, it is of no help one way or the other."

Discussion.

Sir Ronald Ross spoke in high appreciation of the authors' work at the Ministry of Pensions Laboratory. He regarded mononucleosis as of doubtful value in the recognition of past malaria and not to be compared in importance with the finding of parasites or pigment particles, although an increase of the total mononuclear cells was regarded as associated with both sleeping sickness and malaria, but not in his own experience.

Professor Warrington Yorke confirmed Dr. Lucey's observations as to the erroneous increase of large mononuclears shown by the first drop of blood from the ear. He questioned the validity of the results obtained by two different observers, not only in counting two separate drops taken from the same person at the same time, but also in their examination of one film. It was very doubtful whether the two independent counts would be in agreement. Such lack of conformity might show a divergence of as much as 10 or 12 per cent., and be due to the varying distribution of mononuclears and polymorphs in the same film, and to one count being made in the centre, the other along the edges, the most reliable part of the film. Had, therefore, differential leucocyte counts any value at all? He personally regarded them as useless in the recognition of malaria, and the only reliable blood diagnosis was the finding of parasites, after suspending the use of quinine in the case of pensioners under treatment. He asked for a definition of latent malaria, and whether enlarged spleen taken as a sign of latent malaria implied the persistence of parasites in the body.

Professor W. J. R. Simpson paid tribute to the excellent work being done by Drs Broughton-Alcock and his staff at the Pensions Central Laboratory, and was of opinion that their results would prove of the greatest value in the recognition of malaria among pensioners.

Dr. A. Powell, from his experience in Bombay, attached considerable value to the leucocyte count, particularly under the correct technique as detailed by Dr. Lucey, in the differential diagnosis of malaria, seven-day fever, and tuberculosis. He found it difficult to provide an answer to Dr. Broughton-Alcock's question as to the value to be attached to the leucocyte count in malarial cases at home. The conditions varied much in tropical countries compared with those at home, both as to the reliability of patients' statements and as to the circumstances under which blood examinations were made. The personal equation of the counter had to be taken into consideration, and it was therefore of importance that the counts if possible should be made by one observer rather than by several.

Dr. J. Gordon Thomson referred to the time of blood examination during the malarial attack as important. Bailey's observations, that during the paroxysm there was a leucopenia, but in the interval between the paroxysms a leucocytosis occurred due to an increase of the large mononuclears, had been confirmed by David Thomson.

Dr. H. J. B. Fry quoted from observations which had been made on 1083 cases with history of malaria. In 27, or 2·5 per cent., *P. vivax* had been found; the large mononuclear count in 10 of these was above 10 per cent. and in the remaining 17 below 10 per cent. He had not found that the mononuclear count was related either to the period of the fever, the condition of the spleen, the anæmia, or cardiac insufficiency of the malarial cases.

Dr. Basil Price spoke of the diversity of views which had been expressed as to the value of the large mononuclear count, and of the importance of the fallacies as exposed by Dr. Lucey, whose observations, he felt sure, would result in a considerable revision of opinions hitherto held and a revival of interest as to the significance of the large mononuclear cells in the diagnosis of malaria.

Professor Leonard Dudgeon quoted the results of observations carried out on malarial carriers among the British Salonika Force in the Struma Valley during the winter of 1916–1917:—

1. Total number of cases* examined, 2836. — Parasites present in 724.
No parasites present.
Pigmented leucocytes found in 111 cases. — Number of large hyaline cells over 15 per cent in 312.

* Hospital admissions from all causes.

2. Total number of cases examined, 1053. — Positive history of malaria, 1010.
Two relapses or more in 471 cases. — Malaria parasites present in 219 cases.
No parasites found, but large hyalines over 15 per cent. in 399 cases.

At St. Thomas's Hospital during 1919 and 1920 there was no case in the records of the pathological department showing 15 per cent. or more of large hyaline cells, apart from malaria, and only 1 per cent. of cases with a large hyaline cell count as high as 10 per cent. He never took the first drop of blood for film examination, and recalled, as a student, that Professor C. S. Sherrington when lecturing on "The Blood" had warned them to avoid the use of the first drop owing to the fallacious increase in the large mononuclears contained in it.

Dr. A. Castellani regarded mononucleosis of value as a subsidiary aid to the recognition of malaria, and from his experience in Ceylon he had found the large mononuclear increase to persist for a considerable period after an attack, but in greatly varying degree; he was unable to state to what extent this increase and variation prevailed at home as compared with the tropics.

Dr. J. B. Christopherson inquired whether any observations had been made as to the effect of other drugs than quinine on the leucocyte and large mononuclear counts, and what those drugs were.

The President asked how long mononucleosis lasted after malaria. He had found a marked increase of the large mononuclears in active malaria cases due to the benign tertian parasite, especially between the paroxysms, and, as shown by Stephens and Christophers, that increase was present after recent attacks.

Dr. Ernest Black and Lieutenant-Colonel Edmund Wilkinson, I.M.S., also spoke.

Reply to the Discussion.

Dr. Broughton-Alcock, in his reply, stated that he still felt, even after the discussion, the need for the opinion of others as to the duration and degree of the large mononuclear increase among malarial pensioners at home. The use of the term latent malaria was applied to cases sent for quinine treatment, and among them enlargement of the spleen provided the most important clinical evidence of malaria. He quoted an observation made by Craig, in America, in which, out of 1267 cases showing malarial parasites 21 per cent. were cases of latent malaria. The average case usually cleared up at home and did not suffer further after a period of about 12 months. It was very difficult to apply the stoppage of quinine treatment to pensioners in the hope of finding parasites; similarly, as to the time of blood examination, films had to be taken when possible, and no definite time could be fixed. He vainly sought for an answer as to whether the large mononucleosis found in the tropics applied to malarial cases at home, and if the explanation lay in the difference between the two climatic conditions. From his experience in England the large mononuclears, if increased, showed an intermittent rise for a period of less than seven days following a malarial attack, and he gathered that in the tropics this period was considerably extended. Was this ever found to be the case in this country? He asked for a clear definition of the hyaline cells and large mononuclears, and pointed out that Professor Dudgeon's observations in the Balkans had been carried out on persons living under active service conditions in an endemic area and exposed comparatively recently to malarial infection, a state not comparable with that prevailing among pensioners at home. In reply to Colonel Wilkinson's question as to whether any other laboratory sign than mononucleosis was to be found among malarial pensioners, he could say that no other unquestionable laboratory diagnosis existed than the finding of malarial parasites or pigment, as his tables showed. If an increase of large mononuclears was found on the edge of the film it was important to search thoroughly for parasites. He could give Dr. Christopherson no particulars as to the influence of other drugs than quinine on the leucocyte count, but quinine had a leucocytolytic action in causing leucopenia, though leaving the large mononuclears unaffected.

SECTION OF SURGERY: SUBSECTION OF PROCTOLOGY.

PRURITUS ANI.

A MEETING of this subsection of the Royal Society of Medicine was held on April 13th, Mr. A. E. MILES, the President, being in the chair, when Mr. J. P. LOCKHART-MUMMERY opened a discussion on this subject.

Pruritus ani, he said, was a peculiar condition in that it had only one symptom—namely, itching. It had no established pathology, and we were still in the dark as to its cause or the best method of treating it. It was by no means the trivial complaint that its name would imply. The irritation was often so intense as to drive the patient to the verge of madness. The thickening of the skin, the rugæ and eczema, fissures, and other abnormal conditions of the skin around the anal orifice frequently associated with pruritus ani were secondary results of scratching, and beyond the fact that they tended to accentuate the itching and interfere with treatment had no causal relationship to it.

Certain definite types of pruritus ani were to be distinguished: (1) those due to some general condition, such as glycosuria, &c.; (2) those due to some parasite, such as worms, pediculi, &c.; (3) pruritus obviously secondary to some lesion of the anal region, such as fissure, prolapsed pile, &c.; (4) pruritus of old standing where no local lesion can be discovered; (5) paroxysmal pruritus. A local cause for the itching was present in a great majority of cases, and the first essential was to make a thorough search for this cause. Where a definite cause for the pruritus was discovered it was generally one which produced moisture of the parts, more particularly of a septic character, such as fissure or fistula, a polypus of the rectum, or a prolapsed pile. In the case of itching of recent origin removal of the cause was followed by prompt and permanent relief. The difficult cases were those in which no local cause could be discovered, and more particularly the paroxysmal cases, where it was unusual to find any local lesion. With a history dating back for more than two years removal of any local lesion present seldom stopped the itching. It seemed reasonable to conclude that under the circumstances definite changes took place in the skin or in the nerve-endings in the skin. He believed these changes to be of the nature of a fibrosis in the deeper layers involving more especially the end-plates in the dermis and caused by the constant scratching and rubbing. In fact, in these old-standing and severe cases of pruritus an actual disease of the nerve-endings in the skin existed, as was first realised by the late Sir Charles Ball. In 1912 Dr. Dwight Murray put forward the theory that pruritus ani was due to a chronic streptococcic infection of the skin of the anal region. He pointed out that careful investigation by bacteriological methods had proved the presence of *Strept. fæcalis* infection in the vast majority of cases. Mr. Lockhart-Mummery considered that the truth of this theory was now established. In support of it was the fact that a septic lesion was the common starting-point of pruritus. We also know that chronic septic foci of the skin in other parts of the body are frequently accompanied by intense irritation. It is possible that the disease of the nerve-endings in these old-standing cases of pruritus ani is due to this infection rather than to any immediate result of the scratching. Investigation was necessary, but it was difficult to obtain portions of skin for histological purposes, and histological investigation of nerve-endings was itself difficult.

General treatment, such as dieting, non-smoking, total abstinence, &c., Mr. Lockhart-Mummery did not believe in. We ought to try to cure the condition and not to make the patient a slave to his anal region. Rigid attention to local cleanliness and dryness was very important. Lotions and powders were better than ointments. Any local cause, such as fissure, ulcer, pile, hypertrophied papilla, &c., should be removed, and it was often advisable to investigate the anal region under an anæsthetic. Dr. Dwight Murray had suggested the use of a vaccine, but it did not seem reasonable to him, Mr. Lockhart-Mummery said, to treat a septic infection of the skin by vaccine. Antiseptics, such as alcoholic solution of iodine, might be used, either painted on or applied by ionisation. Zinc ionisation or the application of nitrate of silver 30–60 g. to the ounce had given good results. X rays applied to the skin through suitable screens had cured about 20 per cent. of his bad cases. Two or three applications were usually sufficient. It was unwise to persist if marked improvement did not follow two applications.

Operative treatment remained for the cases not remedied by other means. No operation which did not destroy the diseased nerve end-plates in the dermis would remedy old-standing cases. Twenty years ago such cases were treated by excision of the anal skin or the drastic application of the actual cautery. The results were bad owing to the scarring. No such drastic measures were necessary. Sir Charles Ball described an operation for the division of the cutaneous nerves passing to the skin in the anal region. Mr. Lockhart-Mummery had performed it at St. Mark's Hospital since 1905 with excellent results. Other surgeons had condemned it. It was essential that the whole of the irritable area of skin should be rendered completely anæsthetic. The day after the operation the patient should be quite unable to feel the prick of a needle anywhere within the flaps or at the anal orifice. It was easy to miss some of the nerves, but unless they were all divided success could not be expected. In raising the flaps the skin should be undercut well above the level of the internal sphincter. This operation gave immediate relief and left no disability. Normal sensation returned completely within six weeks, generally within four. In the vast majority of cases the cure was permanent. Mr. Lockhart-Mummery had performed this operation in 59 cases; there was a slight recurrence of itching in 7 cases. Four of these were easily cured by simple application, and in 3 cases the operation was repeated with complete success. There was no serious complication, and no patient was kept in hospital or in a nursing home for more than six weeks, the average time being under three weeks. In all these cases normal sensation was restored, and there was no disability.

Discussion.

Dr. ARTHUR WHITFIELD said that, in his experience, pruritus ani was frequently caused by the oxyuris, the presence of which was seldom suspected, and he instanced the case of a lady who consulted him. He suggested thymol, and the patient had one X ray treatment. The pruritus remained quiescent for two years, when the patient again consulted him for the same condition, the thymol treatment not having been carried out. The first dose of 30 gr. of thymol, which was now administered, expelled large numbers of thread worms. Dr. Whitfield agreed with what Mr. Lockhart-Mummery had said with regard to local applications. Grease should be avoided, but if used it should be thin and not sticky. He practically never used X rays. In his experience the first dose cured, but there was a relapse after a few weeks, which was cured by a second dose. The cure was not permanent and the time came when it was no longer safe to give further applications and the condition remained unrelieved. When there was an obvious cause which could be removed one dose of X rays produced a cure, but X rays should be avoided if possible.

Mr. J. M. H. McLEOD said that pruritus ani was only a symptom. He had known the condition to have been caused by congestion of the liver resulting from the taking of coffee, red wines, &c., the pruritus coming on about half an hour after the ingestion of the article of diet or condiment which was at fault and lasting one to two hours. Many cases were due to cutaneous lesions. He instanced a case in which it was due to a patch of psoriasis around the anus, the other patches being trivial. He had also seen a couple of cases due to ringworm. He thought that the itching produced a thickening of the epidermis, which pressed upon nerve-endings and caused spasm and pain, a vicious circle being thus formed. Quite a number of his cases had done well with X rays. He had also used radium but was not very pleased with it.

Sir CHARTERS SYMONDS insisted upon the need for cleanliness and dryness. The application of wool would prevent friction; he preferred salicylic wool. He advocated the use of organic silver preparations, such as protargol or argyrol, in 10 per cent. to 20 per cent. solutions. They were non-greasy and should be put on after the part had been cleansed with lysol and dried thoroughly.

Mr. N. S. FINZI said that where the cause had been removed or no definite cause could be found the theory of infection of the skin was very feasible. In such cases local treatment—e.g., X rays—was a sound proceeding. The condition was always relieved by X rays to begin with, but in a large proportion of the cases the symptoms recurred. The results with radium were more permanent, he thought, than with X rays. If the irritation involved a wide area he preferred radium. He gave full doses of X rays at intervals of three weeks, and one or two doses after the irritation had disappeared. He gave radium at intervals of six weeks, and one treatment after the irritation had gone. High frequency sometimes produced a remarkable effect.

Sir CHARLES GORDON WATSON said that certain cases were medical rather than surgical. Such were those which occurred in neuropathic individuals or patients with an hereditary tendency—functional cases. He instanced the condition occurring in father and son. Surgical cases could be divided into two classes: (1) those in which there was a real cause at the anus, and (2) those in which there was *no marked disease*. Cure was doubtful when dermatitis was well established. While the skin remained pliable the condition did respond to ionisation. In 1909 he had treated 28 cases with zinc ionisation which was followed by much relief after the first treatment. Many patients had had 5, 6, or 7 applications. When the condition was paroxysmal some cases were functional and some, he thought, were due to hypertrophied anal papillæ. Out of 86 of his cases of pruritus ani at St. Mark's Hospital, 53 had visible papillæ. In order to determine the proportion of cases in which the papillæ were visible normally, a colleague at St. Mark's had examined a series of patients who attended the hospital, and 12 out of 50 had visible papillæ. In these cases of hypertrophied papillæ cure could be brought about by cauterisation of the papillæ.

Mr. ASLETT BALDWIN said that there was one condition which he had found in a number of cases. Examination should always be made by the sigmoidoscope for a catarrhal state of the bowel. This he treats by zinc ionisation, filling the bowel with a solution of zinc sulphate. He also uses zinc ionisation locally. He had found the local application of hazeline cream useful, and also painting with tinct. benzoini co.

Dr. I. FELDMAN agreed with the previous speaker with regard to catarrh of the bowel, and spoke of a patient who complained of continual oozing from the bowel. With regard to heredity, he told of a case in which the patient's father had also suffered from pruritus ani, and his grandmother had had pruritus vulvæ. Dr. Feldman insisted upon the need for keeping the bowels well opened.

Mr. FRANK COPE spoke of the paroxysmal nature of the complaint, in which it resembled asthma. In an American paper cases had been reported which had been subjected to skin tests and reacted to pork and potato, and the taking of or abstention from pork or potato brought on or alleviated the condition.

The PRESIDENT differentiated between pruritus due to a local condition affecting the peri-anal region and that which was *part of another disease*. A particular cause was dampness of the anal region due to hyperactivity of the skin in that region. He thought that hypertrophied anal papillæ were present in the majority of cases of pruritus ani. Their most productive cause was rectal constipation, where there was a collection of fæcal material where it should not exist. In the anal papillæ was a large profusion of nerve terminals, *in which was situated a special rectal sense to guard* against the involuntary discharge of fæces. Rectal constipation produced a muscular spasm, so that the rectum was not completely emptied. The treatment he advocated was to keep the anal region dry and to ensure the emptying of the rectum at night, which could be done by introducing half a pint of water at a temperature of 70° to 80° F. He was sure that 80 per cent. of the cases could be cured by dryness, cleanliness, relieving constipation, and removing any obvious cause. Another 10 per cent. might require other treatment, such as zinc ionisation (which was extremely good) or X rays. The remaining 10 per cent. were patients with neurotic tendencies, who would defeat all efforts and remain permanently to remind us that there was a limit to medicine and surgery.

Mr. LOCKHART-MUMMERY briefly replied.

SOCIETY OF SUPERINTENDENTS OF TUBERCULOSIS INSTITUTIONS.

A SPECIAL meeting of this society was held at 122, *Harley-street, on April 11th, when the* reports, previously circulated, of several special committees were further considered.

Report No. 4 (Diet in Tuberculosis Institutions): certain points were discussed. On the question of a special diet for hæmoptysis cases Dr. MARCUS PATERSON said he saw no necessity for altering the ordinary diet, and quoted Dr. Leonard Hill as writing that he knew of no evidence showing *that lowering the diet lowers* the blood pressure.—Dr. F. R. WALTERS agreed, and stated he would diminish fluids only.—There was a marked difference of opinion upon the place of milk in the diet. Most agreed it was only necessary in the case of patients markedly under-nourished. Likewise on the quantity of meat a lively discussion ensued. Drs. J. WATT and W. C. FOWLER thought 10 oz. of meat a day "as purchased from the butcher" ample; but Drs. PATERSON, T. G. PUGH, A. C. TA'BOIS, and P. W. EDWARDS disagreed and suggested it would be a better method of deciding the amount to take "cooked meat."—After further discussion the report was referred back to the subcommittee to come up again on May 30th.

Report No. 5 (Residential Treatment of Advanced Cases of Tuberculosis) dealt with all cases unsuitable for sanatoriums and cases likely to die within one month, including the "acute early" case. Dr. NIVEN ROBERTSON thought the inclusion of the "acute early" case bad for the moral of these cases, even if good for the more truly advanced case and for the nurses.—Dr. PATERSON said that this was overcome by the provision of small wards.—Considerable discussion ensued on the exclusion of the case likely to die within one month. Dr. PATERSON said the committee had in mind, not cases transferred from another institution, but cases sent direct from their own homes.—Drs. WATT, S. V. PEARSON, and EDWARDS thought that even such cases should be admitted both in the interests of the community and of the comfort of the patient and his friends.—There was almost unanimous opposition to small local homes; but opinion was divided about making use of certain wards in infectious hospitals, for though medical supervision might be arranged, yet the skilled nursing would be absent.—*The report was referred back.*

Report No. 6 (Classification) revealed unanimity of opinion, except for minor points. The impossibility of any classification owing to the great factor of the character of the patient was pointed out. Dr. H. A. ELLIS thought that rectal temperatures or 15 minutes in the mouth were impossible for a dispensary, and that a more general, even "slacker," classification was needed for dispensaries, with a more accurate one for sanatoriums.—It was pointed out that hilus disease was not taken into account, nor yet X ray findings. To clear up a few small points the report was referred back to the joint committee with the tuberculosis group of the Society of Medical Officers of Health and the Tuberculosis Society, which is considering classification.

The next meeting was fixed for 4 P.M. *on May 30th.*

SOCIETY OF MEDICAL OFFICERS OF MATERNITY AND CHILD WELFARE CENTRES.

A MEETING of this society was held on April 15th, Dr. H. C. CAMERON, the President, in the chair.

Dr. MARION COCKERELL read a paper on

Infant Feeding after the Ninth Month.

She emphasised the fact that babies appeared to thrive under astonishingly different diets, especially when given a plentiful supply of fresh air. Overcrowding was bad not only in itself but also because regular feeding was difficult to maintain in tenement houses and flats, where the crying child had to be pacified at night at any cost. In reviewing recent advances in our knowledge of dieting children Dr. Cockerell said that vitamin research had not given rise to any remarkable changes, since butter and cod-liver oil had always been recommended, but had warned us against the dangers of over-cooking. The importance of selecting specially digestible food for young children appeared to have been over-rated. Vegetarians fed children on salads without ill-effects; and whereas in London plums off a barrow often appeared to upset children, an indefinite quantity of plums picked direct from the tree was not, in her experience, harmful. Dr. Cockerell spoke of the importance of prophylaxis against dental caries, and quoted Dr. J. Sim Wallace's views on the need of supplying such a diet as would promote mastication, even in the very young, because of the mechanical cleansing effect of a flow of saliva and of its ptyalin content. Dr. Cockerell, after pointing out that it was unscientific to assume that the infants actually get what the doctor advises, gave details of the diet recommended by her. From the ninth to the eighteenth month she advised milk, fresh or dried, and crusts spread with butter or dripping. She saw no reason why the child should have barley jelly, or any other carbohydrate beyond what it was able to extract from biting and tearing at crusts, which it appeared to be able to masticate quite well without teeth. Madame Montessori apparently gave slops only till the children reached 5 years on the plea that the masticatory powers were still undeveloped, and it would be interesting to find out the condition of the teeth of children thus fed.

Dr. Cockerell allowed eggs at 12 months, fish at 18 months; three meals a day only, and nothing but water between meals. Milk pudding should be made stodgy, so as to require mastication, and baked suet puddings were better than boiled. A terminal apple or orange was advisable for cleansing purposes—and if these were economically impossible she advised mothers to give lettuce or other salads, or even cheese or nuts, provided the child was a good masticator. Most children were given too much sugar. Dr. Cockerell deplored the habit of giving sweets between meals, and recommended that foods should not be made sweeter than sweet fruits. During the war men missed sugar more than children did, as their palates had become used to it.

Discussion.

Dr. HAROLD WALLER asked what quantity of milk daily was recommended by Dr. Cockerell. An obsession as to the need of large quantities of milk appeared to swamp infant welfare centres. Milk was an ideal food for the sick child, but an enormous amount of rules had swept over from the sick-room to the centre without being questioned on the way. In Dr. Waller's opinion not more than half a pint of milk a day was advisable if the child was to thrive. An arbitrary period of nine months as a fixed point for a change of diet was not wise or practical, as the period at which a child reaches a certain stage of growth is variable. On questioning the parents of fine, healthy babies he had ascertained that parents usually discovered how best to feed them by the method of trial and error till they found what the child could take, and sometimes the baby throve excellently on a most varied diet below the age of 9 months. He himself was not at all afraid of feeding a massive child of 5 months on eggs and suet. Dr. Waller had arrived at these conclusions by choosing specially fine healthy babies and then finding out what they were fed on. Among the poor in his district cow's milk played no part in the feeding of infants, who were often gloriously healthy, and inasmuch as they lived in cellars and had but little fresh air, their well-being could only be attributed to their diet, which often resembled that of their parents. During the war the Government expressed horror that no milk was available for the poor. But the poor did not use it and there was no reason why they should. Bread fried in fat, dripping, and suet puddings supplied all the fat necessary.

Dr. ERIC PRITCHARD said that children were usually correctly fed up to 9 months, and rules were then cast aside. In his opinion the error in most diets from this age was the enormous excess of nitrogenous food offered. He gathered that Dr. Cockerell was not enamoured of "balance" in food, but he regarded this as essential. At nine months nothing happened to call for a great change except that growth was less rapid and the child moved about more—thus less nitrogenous and more carbohydrate food should be offered, but the reverse was the usual practice. As to teeth, much the most important criterion was the appearance of the teeth when erupted. Dr. Pritchard found it difficult to believe that well-formed teeth could be damaged by the presence of acids in the mouth. Dr. Wallace assumed that acid in the mouth was sufficient to cause caries, but this acid was neutralised, and the only question was whether there were sufficient alkaline reserves available for this purpose. This again depended on whether the child had passed through a modified rickety condition or not. As to milk puddings, why should they not be made into biscuits? Incidentally Dr. Pritchard had never understood why there was such a strong feeling against pastry for babies. It was composed of carbohydrates and fat, as was a milk pudding. A milk pudding in biscuit form provided excellent food and needed mastication; if given carbohydrates in the form of slops the child acquired a reflex to swallow this type of food without mastication. As to milk, Dr. Pritchard had calculated that at 9 months a pint and a quarter of milk contained all the nitrogenous food required. More led to intoxication, and should not be given. He felt sure that the milk question had been overdone.

Dr. R. C. JEWESBURY advocated the type of hard crusts recommended by Dr. Truby King, consisting of slices of bread baked in a slow oven until brick-hard. The child was given these at six months; they were not allowed to get sodden, nor was the child allowed to swallow pieces. Later on starch was introduced in the form of barley jelly. This was given because it was easily prepared, was digestible, and could be carefully graduated, the amount starting with a teaspoonful morning and evening, gradually increased. After the ninth month the milk mixture was gradually strengthened, but whole milk was not given till the eighteenth month. After the tenth month other forms of starch were given. Dr. Jewesbury inquired as to Dr. Cockerell's system of graduating the supply of carbohydrate. An objection to excessive milk feeding was its constipating effect.

The PRESIDENT suggested that all articles of diet need not require mastication any more than all need contain vitamins. A child should not be fed only on hard food; soft food need not be abandoned entirely. He did not agree with the theories propounded by Dr. Wallace. In the mouths of children with well-shaped teeth no trace of food could be seen ten minutes after soft pultaceous food had been consumed; if crevices were present, of course, bits of food were still visible. Dr. Cameron added that the important factor must surely be in the formation of the enamel organ, and in that good development of the mouth and jaw which was dependent on correct breathing habits. The adenoid facies was produced in quite tiny infants by nasal obstruction. The importance of correct diet lay not so much in its mechanical effect emphasised by Dr. Wallace as in its suitability in building up resistance to infection. As regards milk, this food proved a convenient vehicle for giving the child fat in a palatable form. As to the vitamin question, Dr. Cameron could not believe rickets was due to lack of a vitamin; in the experimental evidence offered half the quantity of the fat given would anyhow have had to be administered to the puppies.

Dr. MARGARET ALDEN said that one advantage of milk was that the child got water that way; it was difficult to persuade mothers to give water by itself. She asked whether bacon fat could properly be recommended, inasmuch as lard had a low vitamin content.

Dr. FLORA SHEPHERD suggested that a balanced diet was important, but it was immaterial whether the child got it from milk, eggs, or in other form.

In reply, Dr. COCKERELL said that the amount of milk recommended to babies after the age of 9 months varied with the amount of crusts consumed. The maximum quantity ordered was 1½ pints, and after the age of a year not more than 1 pint was advised. As to the composition of the dietary, after 9 months she had not tried to make it approximate to that of the mother's milk. The amount of carbohydrate was left to the child's own appetite. It was not likely to overfeed if it had to work for its food.

SOCIÉTÉ DE THÉRAPEUTIQUE DE PARIS.

AT a recent meeting of this society MM. A. MARIE and FOURCADE read a paper on

Opotherapy and the Menopause,

in which they remarked that every alienist knew how dangerous the menopause was in neuropathic subjects, as well as in women with renal or hepatic insufficiency. Obsessions, phobias, melancholia, acute hallucinatory confusion, and more or less systematised persecutional insanity were frequently observed in the period preceding, accompanying, or following the menopause. MM. Marie and Fourcade were convinced that the suppression of the menstrual flow was not the only cause of these symptoms, but assigned the chief rôle to a deficiency of the endocrine glands, especially of the thyro-ovarian secretion, as maintained by Hutinel. They had therefore made a systematic use of opotherapy in all the mental disorders of the menopause. After a preliminary period devoted to a disintoxication of the system, in cases where a slight hepato-renal insufficiency was present, opotherapy was instituted, consisting in all cases of thyroid and ovarian extract or extracts of other endocrine glands in the presence of symptoms indicating their insufficiency. The histories of eight cases were recorded, in six of which considerable improvement occurred, and in two no result was obtained from this treatment.

Permanganate of Silver in the Treatment of Urinary Diseases.

Mr. P. GALLOIS in his paper drew attention to the greater efficacy of permanganate of silver as compared with the potash salt in the treatment of urinary disease. The doses used were 0·05 g., or 0·10 g. per litre for gonorrhœa or cystitis. The only drawback of permanganate of silver was that it was slightly more caustic than permanganate of potash. The pain, however, caused by it was not very persistent, and lasted only a few minutes.

In a paper entitled

Can the Diabetic Patient be Allowed to Grow Thin?

Mr. P. RATHERY answers the question as follows. Loss of flesh in diabetes may be allowed, provided the patient is stout and a large eater, and the loss of flesh is confined within certain limits. He may also be allowed to lose flesh *temporarily* as the result of a relative or absolute starvation regimen. With these exceptions a diabetic patient should not be allowed to grow thin. Loss of flesh due to dietetic errors can easily be corrected. Lastly, the loss of flesh may be pathological, indicating either a more or less latent tuberculosis or some serious disturbance in the carbohydrate metabolism.

Patent Foods and the Question of Vitamins.

MM. ÉMILE PERROT and RAOUL LECOQ, in a paper on this subject, described their observations on white rats which had been fed on a diet entirely composed of patent foods. The changes in weight, retardation of growth, and other disturbances showed that, with rare exceptions, these so-called "complete foods" were entirely inadequate.

The Serbian Hydromineral Station of Vrinci.

Mr. TCHÉDA MICHAÏLOVITCH, of Belgrade, in his paper stated that Vrinci was the best known thermal station in Serbia and the neighbouring countries. It was first discovered in 1834 and gradually developed, until in 1912 it was visited by 14,000 patients. It possessed at present two springs, one hot and the other tepid, with bicarbonate of soda as the principal ingredient. The Vrinci waters were indicated generally in all affections of the mucous membranes, but the great majority of the patients were suffering from gastro-intestinal or pulmonary disease.

The Use of Manganese in Debility.

MM. Camescasse and Bisot drew attention to the excellent results obtained by administration of binoxide of manganese in doses of 0·03 to 0·07 g. daily in children whose growth was retarded, as well as in chlorosis in girls and hæmophilia in boys. The treatment lasted three months, the drug being given for 12 days at a time.

The Treatment of Tachycardiac Neuroses by Hydrotherapy.

Mr. R. DUBOIS recorded three cases, two of which presented Continuous Tachycardia and one Paroxysmal Tachycardia, which were much improved by hydrotherapy. The method employed was as follows: During the first three days a tepid douche of a temperature 98·6° F. was given for one minute. The following three days the douche was followed by a cold affusion at 53·6° F. for 10 seconds. After the seventh day the cold douches were given for 25 seconds. Examination of the patient's pulse before and after the douche showed that there was often a difference of 30 or 40 beats. The sedative action of the cold douche which was temporary at first gradually became persistent, and the tachycardia disappeared. At the same time there was a slight fall in the blood pressure, which was always somewhat raised in these patients.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.

A MEETING of this association was held on April 12th at the Elizabeth Garrett Anderson Hospital. In the absence of Mrs. FLEMMING, the President, the chair was taken by Lady BARRETT.

Dr. JANE WALKER read a paper on

Tuberculosis in Children of School Age,

basing her observations chiefly on her experience at the East Anglian Children's Sanatorium. She pointed out that the importance of the question of tuberculosis in children had become recognised, largely as a sequel to the establishment of a school medical service. Most people agreed that tuberculosis is usually acquired in childhood, though its exact prevalence is still quite unknown, the percentage of incidence given by different competent authorities varying from 2 in 300 to 15 per cent. The disease in children was usually insidious in onset, though very rarely the onset might be sudden, with hæmoptysis or pleurisy. Dr. Walker's statistics showed that out of 800 children treated at the East Anglian Sanatorium 1·5 per cent. gave a history of hæmoptysis at onset, 20 per cent. a history of cough, and a small number dated the illness from an attack of whooping-cough, still fewer from measles. The duration of symptoms before treatment was sought varied from five years to one. Differential diagnosis had to be made between tubercle, rheumatism, and chronic gastro-intestinal catarrh. Rheumatic cases did not respond to treatment, while cases with intestinal disturbance are proved able to digest fats only with difficulty. Statistics taken at King Edward VII. Sanatorium showed that the fact that a child came from a home where there was definite tuberculous disease did not apparently make its prospects worse. Infection by contact appeared to be a far more important factor than infection due to hereditary predisposition, but it was often difficult to find the source of infection. The presence of T.B. in the sputum was of vital significance; where they occurred in children the seriousness of the case was enormously increased. From 1914 to 1919 at the East Anglian Sanatorium, 62 per cent. of the 807 children had T.B. in the sputum, and of these 56·4 per cent. died. Results of treatment in cases where T.B. did not occur in sputum were very good. 85 per cent. were sent home really well, and only quite a small percentage of these needed further treatment. As for diagnosis in early stages, this was very difficult by physical examination of the chest alone. Dr. Walker pointed out the importance of training the medical profession in the recognition of early signs of the disease, and suggested that a linking of hospitals and tuberculosis dispensaries would be of much value to this end.—A discussion followed, in which Dr. Rose Jordan, Dr. C. A. King, Mrs. Hogarth, Dr. Flora Shepherd, Dr. Mary Gordon, and Dr. A. Parsons, joined.

Reviews and Notices of Books.

DIABETES.

1. *Le Diabète Sucré. Etudes Cliniques, Physiologiques et Thérapeutiques.* By Professor MARCEL LABBÉ. Paris: Masson et Cie. 1920. Pp. 376. Fr.20.
2. *Diabetes.* A Handbook for Physicians and their Patients. By PHILIP HOROWITZ, M.D. New York: Paul B. Hoeber. 1920. $2.

1. This book is mainly composed of clinical lectures and papers which have been published in various French journals. With one exception they all appeared before 1915, and as our knowledge of diabetes has increased considerably since that time it is inevitable that some of them should be out of date. The method of publishing collected papers in book form suffers from the drawback that it involves much repetition. No less than three chapters are devoted to the treatment of coma by alkalies. The author divides cases of diabetes into two classes, those without and those with loss of weight. He describes the symptoms of both these types as illustrated by cases and their treatment. Treatment consisted in reduction of carbohydrates, but the need of a high protein diet is emphasised for the cases with loss of weight. Treatment by starvation is described as a possibility, but is not recommended except for fat patients. Allen's work is barely mentioned and the author has no appreciation of its value. While the early diagnosis of coma is considered at some length, no allusion is made to the importance of estimating the percentage of carbon dioxide in the alveolar air. Coma was treated with massive doses of alkalies, but starvation was not employed to avert its onset. The book contains some articles which are of special interest. Chapter XIII. consists of a clinical lecture on bronzed diabetes, and gives a good account of its pathology. Chapter XVI. is an interesting record of a patient who developed glycosuria about 20 years after the onset of the symptoms of acromegaly.

2. Dr. Philip Horowitz's book is designed to bring about intelligent coöperation between the doctor and the patient. It is not intended to supplant the doctor, but to teach the patient a little about the disease and a great deal about diets. The treatment advocated is the modern one of Allen and Joslin, an adequate account of which is given. Accounts of cases are given, and as the book is intended for patients the mild ones are fully described, while the severer ones are barely touched on. Instruction about diet is very full, but the recipes lose a little of their value for English readers, as the patent preparations are all American. A good table of the protein, fat, sugar, and calorie contents of foods is provided. The patient is urged to test his own urine. Benedict's reagent is recommended for sugar and the ferric chloride test for aceto-acetic acid, but the common error is made of saying that the nitro-prusside reagent is a test for acetone, whereas it is a much better test for aceto-acetic acid.

TRIAL OF THURTELL AND HUNT.

Edited by ERIC R. WATSON, LL.B., of the Inner Temple, Barrister-at-law. Notable Trials Series. London and Edinburgh: William Hodge and Co., Ltd. 1921. Pp. 217. *10s. 6d.*

THE murder of William Weare by John Thurtell near Elstree on Oct. 24th, 1823, ranks as a classic, because after having excited a prodigious amount of public interest as a blood-curdling crime it found its way into literature. Carlyle[1] and George Eliot both refer to the attribution of respectability to a man who kept a gig, apparently put in the mouth of a witness by the *Quarterly Review*, as Mr. Watson finds no authority for it in the reported evidence; Borrow and Pierce Egan were familiar with the murderer's career; Lytton, in "Pelham," drew inspiration from this crime. It was, however, nothing more than a brutal act of butchery, committed for the joint objects of revenge and gain, and the crime was promptly brought home to its perpetrator owing to his own recklessness and stupidity. He could have, and in fact did, kill his victim single-handed, but he took two fellow ruffians, Hunt and Probert, into his confidence, of whom the latter (hanged in the following year for a horse-theft) was called as King's evidence, and the former was tried with Thurtell, convicted as accessory, and transported. He too had hoped to be made a witness, and he did all he could to save his own neck and hang his principal by showing where the body had been hidden. The murder of Weare, a person deserving no particular sympathy, is justifiably included in the "Notable Trials Series" on account of the features above mentioned, not on account of any legal, scientific, or romantic interest attaching to it, or any display of astuteness by the authorities in its detection. Mr. Eric Watson, who has edited the story of the trial, has been at considerable pains to render the volume for which he is responsible authoritative, and, in the interests of strict accuracy, the editor of the Dictionary of National Biography might take advantage of his research if ever the volume containing the name of Thurtell comes up for revision. Mr. Watson is not, however, always to be congratulated upon his style, which has a tendency towards the conventions of Victorian journalism. For example, when he wishes to record that the Thurtells kept a public-house, he tells us that "the brothers decided to tempt fortune in the *métier* of Boniface."

The medical evidence at the trial was of the simple character to be expected.

> "*His throat they cut from ear to ear*
> His brains they punched in.
> His name was Mr. William Weare,
> Wot lived in Lyon's Inn."

That is Mr. Watson's version of the well-known ballad, and the first two lines quoted indicate roughly the injuries deposed to by Mr. Thomas Ward, surgeon, of Watford. He bore out Probert's report of the murderer's own account of how he had fired his pocket pistol without effect, had cut his victim's throat, aiming at the jugular vein, and then "jammed the pistol into his head," fracturing his skull by driving the muzzle into it with repeated blows. It is satisfactory, however, to note that Mr. Justice Park, in summing up, said that Mr. Ward had given his evidence "in a manner highly creditable to him as a professional man and a gentleman."

The maps included by Mr. Watson will enable any good walker or curious motorist from London to visit the scene of the murder. He will not find Probert's cottage, any more than he will find Lyon's Inn in the Strand between Holywell-street and Wych-street, for the cottage, we believe, was pulled down about thirty years ago. He may, however, be able to trace the garden where the body was at first hidden in a pond, and he should be able to identify with tolerable exactness the spot where Weare was killed. In doing so he will tread in the footsteps of Sir Walter Scott, who made the same pilgrimage nearly a hundred years ago.

MONOGRAPH ON INDUSTRIAL CHEMISTRY.

Plantation Rubber and the Testing of Rubber. By G. STAFFORD WHITBY, Ph.D. London: Longmans, Green, and Co. 1920. Pp. 559. 28s.

THE development of the automobile is largely responsible for the enormous expansion which the rubber industry has undergone during the last ten years. The world's output of raw rubber was, in 1917, more than three and a half times that of 1910, this increased production having been absorbed chiefly by the United States. Whereas rubber used to be obtained from inaccessible forests, it is now for the most part derived from the plantations, where its preparation can be carried out under proper technical control, and new and far-reaching possibilities are thus opened up for the industry.

---

[1] Carlyle: Miscellanies, vol. ii., p. 144. According to Carlyle's note the witness was speaking of Weare, but Probert also owned a gig, and Thurtell hired one for the purpose of the murder.

In Part I. of this volume Dr. Whitly describes the preparation of plantation rubber from the tree stage to the finished product. The subjects are dealt with in a clear and fairly detailed manner and with numerous references to the scientific and technical literature. This portion of the work should be read by those who are financially interested in rubber. Part II. is concerned with investigations relating to the physical properties of rubber, such as the modulus of elasticity, the technique of tensile and of vulcanisation tests, viscosity determinations, the relation of the thermal, optical, and electrical to the mechanical behaviour of rubber, and so forth.

The work is well written and freely illustrated, and may be recommended confidently to those who are associated in any way with this great and increasingly important industry.

MANUAL OF NURSING PROCEDURE.

By AMY E. POPE. London and New York: G. F. Putnam's Sons. 1921. Pp. 596. 18s. 6d.

As announced in the preface of this useful book, it has been prepared especially to facilitate teaching by demonstration of such practical nursing as is usually included in the first year of instruction, and it can be highly recommended to ward sisters and sister tutors. It should be a valuable aid in the correlation of theory and practice since the author has included with each demonstration its physiological basis where knowledge of this is essential to the intelligent carrying out of prescribed treatment. To appreciate the psychology of nursing is as important to the student as acquiring a vast knowledge of physiological facts and nursing procedure, and the author has realised this in a valuable chapter on some of "The Routine Procedures Incidental to the Comfort and Care of Patients." The instructions given in this chapter embody the very essence of good nursing, founded on a sympathetic understanding of the mind of the patient, and the formation of good nursing "habits."

Although the book can be highly recommended to instructors and nurses alike, we may remark that the addition of more illustrations would have increased its value, and at the same time obviated the need of verbal explanations not always very clear.

AMERICAN YEAR-BOOK OF ANÆSTHESIA AND ANALGESIA (1917–18).

Edited by F. H. MCMECHAN, A.M., M.D. New York: Surgical Publishing Company. Pp. 483.

THIS annual publication has suffered delay owing to the war, but a great part of its contents owe their value to the same cause. A large number of contributions describe the practice of anæsthetics at military hospitals near the line and at the base, and enumerate the lessons taught to the anæsthetist by military surgery. Several of these papers have already appeared in English journals. Of the other articles, some deal with circulatory disturbances under anæsthesia, with pharmacology and physiology of general anæsthetics, with blood changes, and with special methods of anæsthesia. W. E. Muns contributes a paper on the effects of ether anæsthesia and visceral trauma as shown by vasomotor and blood-pressure changes. The experiments show how, by two different routes, the one being continued stimulation and the other prolonged depression, the end-result is the same—functional incapacity—whether brought about by excessive trauma or by anæsthetic over-dose. A paper on blood-pressure guides during operations shows how the sphygmomanometer may indicate the beginning of shock before this can be discerned by alteration in the pulse-rate, and also how asphyxial changes may be signalled by blood-pressure alteration before they are obvious to the naked eye. The readings were taken at least every five minutes. Pre-operative blood-pressure tests have been used by G. W. Roots to formulate a rule for operative risks. Similarly, McKesson states a rule for measuring the severity of shock during operation. J. O. Pollak discusses pulse pressure as the pre-operative index of cardiac strength. A paper on Warmed and Unwarmed Ether Vapour contains the statement that there is no satisfactory theoretical or experimental evidence that anæsthetic vapours are made less toxic by being warmed. The volume is a valuable one, but not quite the equal of its predecessor.

OUR SOCIAL HERITAGE.

By GRAHAM WALLAS. London: George Allen and Unwin, Ltd. 1921. Pp. 292. 12s. 6d.

THE human race owes its present existence to nature and nurture, the latter consisting of two parts, one acquired by each individual for himself, the other consisting of knowledge, expedients, and habits handed down from one generation to another by the social process of teaching and learning. It is the latter which forms the subject of Professor Wallas's entertaining book. From the social heritage in work and thought the author passes on through group and national coöperation to a consideration of professionalism and liberty, and, finally, after envisaging world coöperation, to our present conceptions of constitutional monarchy, science, and the church. His views on the medical profession betray no close acquaintance with the subject.

Professor Wallas thinks very meanly of the ability of nature and the individual part of nurture to fit the race for existence. Were every human being now alive to lose all the knowledge and habits acquired from preceding generations, while retaining unchanged his own powers of invention, memory, and habituation, nine-tenths of the inhabitants of London would, he says, be dead in a month, and 99 per cent. of the remainder within six months. They would have no language to express their thoughts, and no thoughts but vague reverie.

> "They would wander about, led by the inarticulate cries of a few naturally dominant individuals, drowning themselves, as thirst came on, in hundreds at the riverside landing places, looting those shops where the smell of decaying food attracted them, and perhaps at the end stumbling on the expedient of cannibalism."

It will be seen from this quotation that Professor Wallas is an advanced disciple of Weismann, and also, as we suggested above, that his book is very entertaining. This applies equally whether he is writing of public school education, of the Mesopotamian inquiry, or of sacramental emotion. And whether the reader agrees with his conclusions or not he cannot escape from the cogency of the author's arguments, by which he will be led gently on from step to step until he may need to call to his aid some hereditary prejudice in order not to have his whole aspect of the external world turned inside out. But here Professor Wallas offers no help, for he does not admit the existence of hereditary prejudice.

A PRACTITIONER'S VADE-MECUM.

Therapeutische Technik für die ärztliche Praxis. Ein Handbuch für Ärzte und Studierende. Fifth edition. By many Authors. Edited by Dr. JULIUS SCHWALBE. Leipzig: Georg Thieme. 1921. Pp. 1120. Price (out of Germany), M.230 sewn, M.260 bound.

THIS is the fifth edition of a mélange of technical detail, collected and arranged by Professor Schwalbe, the versatile editor of the *Deutsche Medizinische Wochenschrift*. The book first appeared in 1907 with the laudable aim of affording the practitioner the opportunity of mastering therapeutic technique, so as to avoid constant reference to specialist help. And the editor's aim has evidently been in large measure successful both in view of the demand for new editions and of translations into Italian, Russian, Spanish, and Magyar. The collaborating authors without exception occupy university chairs in the subjects of which they write, and all branches of medicine are covered except obstetrics, the technique of which the editor considered was sufficiently described in the ordinary text-book. Nothing is left to the imagination or omitted because it is obvious. On the first page, which opens the section of the preparation and use of drugs, is an illustration of a caustic applicator in three parts; in the second section on immuno-therapy is shown the method of giving an intramuscular injection, and all the brands of serum on the market are enumerated;

in the third section on dietetic therapy detailed diet sheets are given for diabetes and oxaluria; section four on hydrotherapy contains numberless photographs and diagrams of baths, douches, and packs; and so on throughout the book. The result is a completeness in trivialities that rather obscures the solid worth of new and exact technique in many specialties. The book is without parallel in any other tongue. H. A. Hare's "Modern Treatment" and A. S. Morrow's "Diagnostic and Therapeutic Technic" are the nearest approach to such a book in the English language. It may also deserve attention from the British or American student as affording a ready method of becoming familiar with German medical terms.

FROM CLOUD TO SUNSHINE: ALGIERS AND ALGERIA.

Tenth edition. By ALFRED S. GUBB, M.D. Paris, M.R.C.S. Eng., D.P.H. London: Baillière, Tindall, and Cox. 1921. Pp. 109. *3s. 6d.*

Dr. Gubb has already published several books, in French and English, on various aspects of Algeria. The volume under review, which is called the tenth edition, but is in many respects a new work, deals with the country as a winter health resort; the new edition is profusely illustrated, and the climate and topography receive careful attention with reference to numerous diseases. Concerning chronic affections of the respiratory tract, we read that physicians of remote antiquity, Celsus (25 A.D.) among them, were accustomed to send their chest patients to North Africa; and Sir Hermann Weber is quoted to the effect that early chronic cases of phthisis benefit by a winter season in Algiers if high altitudes are not well borne by them, and if Egypt and the Riviera are too dry. Freedom from sudden changes of temperature renders the country very suitable for asthmatic persons. Dr. Gubb passes on to mention the climatic advantages for those suffering from kidney and heart diseases, circulatory disturbances, arterio-sclerosis, rheumatism, neuritis, gout, and debility. The therapeutic aspect of Algeria does not, however, occupy the entire book; interspersed with pages on prevailing winds and mineral springs are interesting details concerning the customs and appearance of the inhabitants of the country and the life of the French and native quarters of the city of Algiers, together with notes on the many places of historical and artistic interest which may attract the traveller. Means of transport, hotel accommodation, and useful hints as to selection of a house for temporary or permanent residence, all find a place in an attractive little volume.

JOURNALS.

Journal of Physiology. Edited by J. N. LANGLEY, Sc.D., LL.D., F.R.S. Vol. LIV., Nos. 5 and 6. 1921. Cambridge University Press. Pp. 319-414. *9s.*—The Metabolism of the Salivary Glands. I. The Relation of the Chorda Tympani to the Nitrogen Metabolism of the Submaxillary Gland, by G. V. Anrep. In 1851 Ludwig found that in protracted secretion the submaxillary gland is gradually exhausted and that in consequence the percentage of organic solids secreted in the saliva diminishes as the secretion goes on. Heidenhain in 1868 showed that in the dog the mucin in the saliva arose from a clear substance in the cells, that during secretion the gland lost weight and that the percentage of solids in it is decreased. Dr. Anrep's experiments were directed to the problem of nitrogen metabolism in the secretory process. Having established by the comparative estimation of the nitrogen content and weight of the submaxillary glands of the dog that the two glands show complete concordancy, the determinations justified the assumption that the submaxillary glands on both sides contain practically the same amount of nitrogen. The effect of chorda stimulation on the total nitrogen metabolism of the gland was first determined, then the secretion of mucin nitrogen and non-mucin nitrogen, and subsequently the relation of mucin nitrogen and non-mucin nitrogen to the nitrogen output and intake. Dr. Anrep confirms the old statement that during secretion produced by stimulation of the chorda tympani the output of nitrogen by this gland is greater than the loss by the gland. The excess of the nitrogen output over the loss by the gland increases with increase of output. The output of mucin nitrogen, which, as is known, decreases during secretion, ceases altogether after a time, and is equal to the loss of nitrogen by the gland. The output of the non-mucin nitrogen continues after the output of the mucin nitrogen has ceased, proceeding at the same level throughout the secretion, and is equal to the excess of output over the loss. Its mean percentage in the chorda saliva is 0·018 per cent. The results show that within the limits of experimental error the mucin of the saliva comes entirely from the mucin or mucinogen pre-stored in the gland, that the non-mucin nitrogen is derived from the body fluid, and that no formation of mucin or increase of nitrogenous cell substance takes place during chorda stimulation.

The Temperature Coefficient of the Velocity of a Nervous Impulse, by A. V. Hill. The phenomena of a nervous impulse have been compared with those of a chemical system, such as a train of gunpowder, and Keith Lucas has shown that the velocity of a nervous impulse is increased 1·79 times by a rise of temperature of 10° C. It has been argued that this is a sign of the chemical nature of the changes underlying the propagated disturbance in a nerve. Professor Hill points out that the nervous impulse consists of two separate things: the change at a given point and the transmission of that change to a neighbouring point. At present, however, we are ignorant of the relative importance of the two phases. The temperature coefficient found by Keith Lucas for the velocity of propagation is higher than that of most physical changes. We cannot conclude, however, that the reactions underlying the nervous impulse are chemical in nature, but only that a chemical change interposes *somewhere* in process, occupying a large part of the time of propagation, which may be an important or a relatively unimportant link in the chain of actions constituting the propagated disturbance.

Studies on Muscular Contraction. II. The Relation Between the Maximal Work and the Tension Developed in a Muscle Twitch, and the Effects of Temperature and Extension, by Yasukazu Doi. At a constant temperature the maximal work done by a muscle excited by a single shock has a maximum value with a moderate initial extension of the muscle. Before this optimum extension is reached the absolute maximum work increases, and beyond this optimum it decreases with increasing extension. The absolute maximum work done in a twitch at the same extension of a single muscle is greater at a lower temperature than at a higher. The optimum extension is shorter at a lower temperature than at a higher.

Variations in Alveolar Carbon Dioxide Pressure in Relation to Meals, by E. C. Dodds. All the samples were collected and analysed by the Haldane methods from three healthy men and from a man from whom the greater part of the stomach had been removed. In normal persons the alveolar carbon dioxide pressure showed the following changes after a meal: (1) a rise of from 2 to 6 mm. within the first half or three-quarters of an hour; (2) a subsequent fall of about the same amount (2-6 mm.) below the original level; (3) a return to this level. In the man operated on the rise after a meal was very small in amount (0·4-0·8 mm.), while the subsequent changes were similar to those seen in a normal person. To Dr. Dodds it seems probable that the rise is associated with the secretion of gastric juice, and the subsequent fall with the later processes of digestion.

On the Supposed Identity of the Water-soluble Vitamin B and Secretin, by G. V. Anrep and J. C. Drummond. In 1919 Voegtlin and Myers put out the theory that the antineuritic vitamin and secretin are possibly one and the same substance, basing their view on certain observations. Dr. Anrep and Dr. Drummond find that this suggestion is not supported by experimental evidence—e.g., extracts prepared from yeast which show marked growth-promoting and antineuritic properties have no specific action on pancreatic secretion, differing in this respect from secretin. The pancreas of a cat showing typical symptoms induced by a diet deficient in the vitamin B responds in a normal manner to secretin. Secretin can be extracted from the mucous membrane of the intestines of cats, showing the so-called polyneuritic condition to a very marked degree.

The Action of Ions upon the Frog's Heart, by I. de Burgh Daly and A. J. Clark. The authors' experiments were directed to analyse the effect upon the mechanical and electrical responses of the frog's heart of changes in the concentration of the kations, which are normally present in Ringer's fluid. The effects produced by the various changes of ionic content are obviously of very great complexity. Alterations of the concentrations of the ions, if sufficiently extensive, impair all the functions of all parts of the heart, but a moderate degree of change affects the different regions of the heart to an unequal extent, and also acts with different intensity upon the different functions of the ventricle. Alterations of the potassium content produce a greater impairment of the conduction of the electrical variation, both from auricle to ventricle and within the ventricle than any other ionic change studied. Reduction of the calcium content has little effect upon the conduction of the electrical variation. Potassium and calcium are true antagonists as regards their effect upon the muscular response, but they act as antagonists only to a very limited extent as regards their action on the conduction of the electrical variation. Lack of sodium shows a striking resemblance to the effect of strophanthin. Lack of potassium or sodium and excess of calcium all produce increase of systolic tone in the heart and produce rather similar variations in the electric response; increased alkalinity, which produces increased systolic tone, produces different effects upon the electrical response.

The Immediate Action of Volatile Substances, by W. E. Dixon and Fred Ransom. The object of this paper is the demonstration that the immediate physiological effects produced by certain volatile substances are most readily explained by their physical properties. Two types of experiment were performed: (*a*) on the bronchioles and (*b*) perfusion of isolated organs. The bronchiolar experiments were made on pithed cats, artificial respiration being performed and the blood pressure recorded from the left carotid artery and the condition of the bronchioles gauged by measuring the volume of the middle lobe of the right lung. A great many irritant substances, when inspired in very small quantities, cause broncho-constriction—e.g., ammonia gas, chlorine and bromine vapour; the principal feature of this action is the long latent period, generally 15 to 30 seconds. Chloroform, volatile and possessing little irritant properties and relatively non-poisonous, causes an immediate sudden constriction of the bronchioles lasting 10 to 12 seconds. The first action of alcohol, chloroform, ether, amyl nitrite, petroleum ether, and many other volatile substances administered by inhalation, is to cause broncho-constriction lasting about 30 seconds. The same substances injected into the perfusing fluids of surviving organs of the cat and dog, artificially perfused, cause vaso-constriction lasting about 30 seconds. Professor Dixon and Professor Ransom state their reasons for believing that this action is due to physical processes.

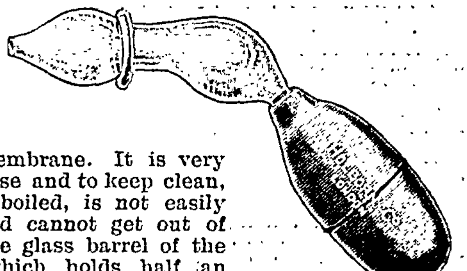
Studies in the Regeneration of Denervated Mammalian Muscle. IV. Effects of Massage and Electrical Treatment in Secondary Sutures, by F. A. Hartman and W. E. Blatz. The tibial nerves in rabbits at the primary operation were severed under aseptic conditions, the cut ends being separated by various procedures in order to check regeneration of the proximal end until the desired time—varying from 1 to 7 months. The denervated legs were carefully protected. When desired the two ends of the nerves were freshened and brought together by suture. The power of the gastrocnemii groups of the two sides was tested by galvanic stimulation immediately after denervation, and at frequent intervals until the conclusion of the experiment. The gastrocnemius group of the right side was treated almost daily by either a slow surging galvanic current or by massage. Of 125 rabbits started in this research, 60·8 per cent. possessed stronger muscles on the right side (gastrocnemius group), the remainder being stronger on the left. Neither massage nor electrical treatment appeared to benefit the denervated muscle.

On the Fibrillation of the Heart, by S. de Boer. If a bloodless heart of a frog is taken, a single electrical stimulus is capable of causing fibrillation of the ventricle. A bad metabolic condition of the heart favours fibrillation. Essential factors in fibrillation are decrease in the rate of conduction and in the duration of the refractory period, so that a circulating excitation can be set up. A single stimulus, in order to produce fibrillation in the bloodless heart, must be applied directly after the refractory period. At this time the excitability of the muscle is slight, and a slowly-travelling contraction with a brief refractory period is produced, so that when the contraction completes its circuit the muscle is again excitable and the contraction can spread again and again round the heart. The stimulus, if applied later, gives rise to a complete coördinated extra-systole. Dr. de Boer concludes, from the deflections recorded in the electrogram and suspension curves of heart peristalsis after poisoning with digitalis and of fibrillation of short duration, that in fibrillation the excitation wave passes round the heart in a series of stages, each being marked by a deflection, and that the *local* circulating excitation assumed by the observers Mines and Garrey does not exist. According to Dr. de Boer's theory fibrillation of the ventricle consists of a linking together of fractionated ventricular systoles.

On Recurring Extra-Systoles and their Relation to Fibrillation, by S. de Boer. When a stimulus is applied to the ventricle of a bloodless frog's heart, a short time after the end of the refractory period, a series of extra-systoles may occur. But when the same stimulus is applied at a longer interval after the end of the refractory period to a heart capable of giving a series of extra-systoles, one extra-systole only is produced. It appears, therefore, that the phenomenon of recurring extra-systoles (Häufung d. Syst.) only occurs when the heart has not recovered its metabolic state. In this state the excitation wave is conducted much more slowly, the refractory period is shorter, and the excitation is able to pass round and round the ventricle—i.e., a circulating contraction is set up. Conduction through the muscle is slowed both in recurring extra-systoles and in fibrillation; the difference between the conditions being that in the former conduction takes place evenly, and in the latter it takes place in stages. The intimate connexion of the two phenomena is shown by the fact that each may pass into the other.

New Inventions.

IMPROVED STERILISABLE URETHRAL SYRINGE.

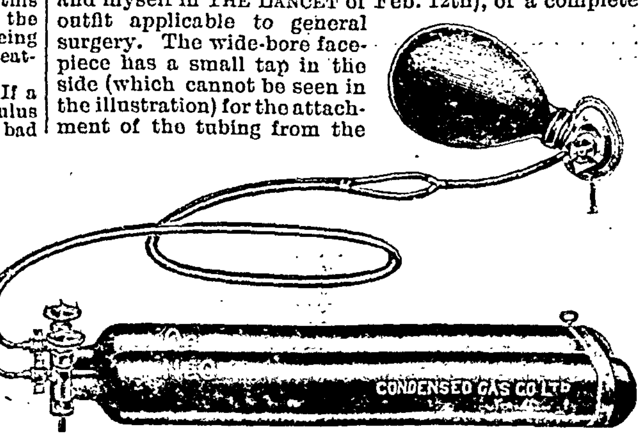


THE illustration shows a syringe shaped to plug the meatus efficiently without causing pain or injury to an inflamed mucous membrane. It is very simple to use and to keep clean, it can be boiled, is not easily broken, and cannot get out of order. The glass barrel of the syringe, which holds half an ounce, can be filled without drawing any fluid into the rubber bulb. The syringe is made by the Holborn Surgical Instrument Company, of Thavies Inn, London, E.C. 1.

FREDERICK H. PICKIN, M.R.C.S., L.R.C.P. Lond.
Westminster, S.W.

CONTINUOUS GAS AND OXYGEN APPARATUS.

THE special features about this apparatus, which has been in use for more than two years are (1) its simplicity (it consists of no more than the essentials), (2) the re-designing of each important part with a view to efficiency, and (3) the formation in conjunction with the warm ether "bomb" (described by Dr. S. R. Wilson and myself in THE LANCET of Feb. 12th), of a complete outfit applicable to general surgery. The wide-bore face-piece has a small tap in the side (which cannot be seen in the illustration) for the attachment of the tubing from the "bomb." The oxygen cylinder valve is the outcome of considerable experiment, differing entirely from other makes. A clip for the ends of the cylinders keeps them rigidly locked together and there are no high-pressure connexions. The design of the stand is for a horizontal position of the cylinders, which are controlled by foot-keys, the gases being admitted in puffs, as desired. An upright stand with hand-control can, however, be supplied. The former method leaves both hands free and is quite satisfactory.



Full particulars can be obtained from the makers, the Condensed Gas Co., Ltd., 59 and 63, Grosvenor-street, All Saints, Manchester.

THE LANCET.

LONDON: SATURDAY, APRIL 23, 1921.

The Position of the Voluntary Hospitals.

THE plight of the voluntary hospitals remains precarious. In recording last week the proceedings at the annual meeting of King Edward's Hospital Fund for London we said enough to show that, especially in the metropolis, great anxiety remains as to the maintenance and conduct of these institutions. There would be no need of pointing this out if it had not been that the whole position appears to be lighter, and there is risk that the public as well as the medical profession should think all danger to be past. The precarious situation of these hospitals was revealed at meeting after meeting and in report after report a few months ago, and then we all knew the serious situation which had to be met. The circumstances leading to the situation have not been modified in any important way, prices have not dropped much, service is not more economical, accident rates have not changed, and only in the incidence of sickness has there been some improvement. All the opportunities for bankruptcy of the hospitals remain, and as long as this is so, it is inevitable that the needs of the institutions should again force themselves upon our attention. What, of course, has happened is that two very large capital sums have been distributed in relief of emergency—namely, £250,000 from the Red Cross and £200,000 by King Edward's Hospital Fund for London—and we have all been sharing in the temporary feeling of ease. This is a state of mind which has to be altered.

We doubt whether the public quite realise that these enormous grants were of an emergency nature and that they were made from capital funds, which means that their repetition cannot be expected. Their receipt by the hospitals enabled the institutions to gain breathing time, and it is obvious that the further strenuous efforts expected must be put into action. In the report of the General Council of King Edward's Hospital Fund for London the special features of the metropolitan hospitals are noted, and the summaries of receipts and distribution present the following outstanding features. The annual subscriptions and donations to the Fund, including £16,000 from the League of Mercy, amounted to £50,000. The London Schools Hospital Fund £10,000, the King George's Fund for Sailors £4000, have to be added, as well as £130,000 from investments and legacies. The Samuel Lewis estate brought £18,000. The total general receipts amounted to £215,800, the discrepancy being due to our not taking account of the small figures in the different items. To this sum is to be added the large sum received from the surplus funds of the British Red Cross Society and Order of St. John of Jerusalem, making, with the interest accrued thereon, over £255,000, and bringing the receipts of the Fund up to the grand total of £471,000. This is a magnificent recognition of the critical nature of the position. There have been distributed £700,000 accounted for in this way; ordinary distribution, £200,000; distribution of Red Cross funds, £250,000; and an emergency distribution of a further £250,000. That is to say that the Fund distributed £230,000 more than it received, and has incurred a capital loss equivalent to an annual income of £16,000. The way in which that money was distributed was set out in detail in THE LANCET on Dec. 25th last, and the only comment it is necessary to make is that the awards were made with scrupulous care and that the needs which were met were of a most urgent character. The last paragraph of the Report may be quoted. "All who believe in the voluntary system must make a special effort to support the hospitals during the present crisis, and to ensure that voluntary contributions form at least a substantial part of their income in the future. The Fund has helped to meet the first need by the emergency distribution of £250,000. If liberally supported by the public it can help greatly with the second, especially in the case of hospitals which are most in need." The Council in their Report acknowledge the debt to the press for the assistance rendered by publicity; the need for this support remains as urgent as ever.

An Interim Report has now been presented to the authorities of King Edward's Hospital Fund by the King's Fund Policy Committee, a committee appointed to work out the details of the policy to be recommended for the preservation of the voluntary system of hospital management and control. The Report is of a highly practical character. The reference of this Committee was a report from the Executive Committee, passing 13 resolutions dealing with the plans to be pursued for the preservation of the voluntary system of hospital management and control. It was required of them to work out the details of their advice, and to recommend the approved measures to the Government, to Lord CAVE'S Committee, and others directly concerned, including the public. Lord CAVE'S Committee, it will be remembered, has already reported that it is desirable in the public interest to maintain the voluntary system of hospital management. The advice of the Interim Committee may be summarised as follows. The Committee finds that the voluntary system must be supplemented, at any rate temporarily, by other sources of revenue, to be derived, first, from payment in some form or other for specific work, and, secondly from public funds. Payment for specific work includes money from public authorities, from individual patients, and from insurance, voluntary and compulsory. With regard to the first, we must look for payments ensured under the National Insurance Act. With regard to the second, a movement to obtain certain payments in certain circumstances from individual patients has been spreading all over the country. No such system was in existence until less than a year ago, but already promising returns have been obtained. With regard to the third, a comprehensive scheme associated with the name of DR. GORDON DILL has been put into operation in Sussex and a committee of the British Medical Association has recommended its adoption with modifications by the hospitals of London.

We have attempted to make a coherent story from the records of much complicated investigation and the moral of that story, already indicated, may be repeated. The voluntary system of hospital support is worthy of every effort for its preservation. While the various Committees whose work has been mentioned have been directing their energies mainly to the metropolis, that work has a direct bearing upon the future of all the voluntary hospitals of the country.

A Solution for the Holiday Huddle.

"*It is easy enough to account for the absurd position that most people's holidays are packed into the same period of opportunity (which is generally the month of August or thereabouts), but it is not easy to see why such a silly arrangement is allowed to continue.*"

WE repeat the opening sentences of an editorial article in THE LANCET a decade ago, as they are just as applicable now as they were then. The English summer still spreads impartially over the months of June, July, and September; often, indeed, May is as merry for the holiday-maker as any of the more orthodox months, and October, in spite of its shortening days, is a kind of Indian summer. And yet, as in 1910, the seaside and holiday season generally is compressed into a month in which accommodation is expensive, hard to get, and crowded, railway companies are more than ever at their wits' end to cope with the sudden demand upon them, and altogether the discomforts and inconveniences are so great that many stay at home in despair, and from a medical point of view there is much to be said for that course. The innocent cause of this prodigious ill is the school child, and its inevitability has never been seriously questioned in any responsible educational organ, though its medical side has been set out for years. A striking article on "No Fixed Holidays" which appeared in the Education Supplement of the *Times* on April 7th breaks the silence in lay journals.

The question of running elementary schools continuously is no new one, and has from time to time been discussed by the London County Council, but on every occasion has failed to gain support, possibly for political reasons and the great convenience of school holidays falling during the recess. And to most of us, whether responsible for the family or the school, the suggestion at first sight raises visions of hopeless disorganisation in the familiar routine of school work, term time, and vacation. Indeed, the initial opposition might be so overwhelming as to veto the proposal entirely. Yet on further and more serious consideration there are undoubted advantages attaching to it. Every business concern and even educational offices are run on continuous lines without any hitch in the machine, holidays being arranged in rotation in order of seniority. Such a system applied to schools, whether elementary or secondary, would necessitate careful planning and arrangement for both teachers and pupils, but it should not prove an impossibility with due coöperation of all concerned and under the control of local educational authorities. It should be possible to arrange without dislocation of school life for the absence of teachers and pupils at regular periods spread over a space of several months, leaving parents some liberty to fix their children's holiday at the same time as their own. The provision of a rota might enable teachers to take each other's duties in turn during the allotted holiday months, with the added advantage of a change of work for a time, when, for instance, the second in charge fills the head's place. Disturbance to class work by the withdrawal of children at various periods ought not seriously to interfere with the continuity of their studies; coming back invigorated by the holiday's change the average pupil should have little difficulty in making good lost ground. Only a rigidly mechanical conception of education can think or speak of the loss as irremediable. Pupils in a class differ too widely among themselves for the absentee to upset the whole system. There are, of course, many children in the elementary schools whose holidays are spent in the streets, the various playgrounds and parks, without prospect of any other change. For these a longer choice in summer might make it possible to arrange for school journeys or camps for periods spread over the several months under the voluntary charge of assistant teachers or other helpers.

The question of the influence of the continuous school system on the course of epidemic and infectious diseases among school children is one, nevertheless, which would need careful consideration. At public schools the beginning of the term is always an anxious time, and day boys constitute a complicating factor in the boarding-school system. The objection would not apply in the same way to elementary schools or to day schools in general. A good deal, on the other hand, is to be said of the strain on all teachers inevitably attaching to the heavy work in the schools at the close and commencement of each term, which the continuous system would do away with. The new continuation classes, if they are to survive, must necessarily run continuously, as those attending them being in employment have no fixed holidays. Is it too much to hope that the suggestion will receive serious consideration upon its merits? Some body similar to the Industrial Research Board might be asked to report upon its actual balance-sheet in work and efficiency.

◆

The Question of a Trade-Union in Medicine.

IT may be remembered that last autumn in certain mining districts there was a definite movement among medical men to cease work unless their clients paid higher fees. The whole question of a strike among doctors was freely discussed at the time in the lay papers, and while no representative gathering of medical men expressed any opinion on the subject, it was dealt with in a certain number of resolutions. At those medical meetings where the question of a medical strike was debated the conclusion come to in almost every case was, if we remember rightly, that a strike of doctors was unthinkable. It was pointed out on each occasion that even if medical men desired to adopt union tactics to obtain their dues, and even if hard situations, as they arose, could be remedied in such a way, they did not possess a union. And none of those who seemed to regret the fact were able to outline the constitution of a trade-union for medical men which should alike have the powers of the well-known combinations and be able to exercise those powers concomitantly with the discharge by its members of their professional duties.

The story of the past fortnight makes the subject of a medical strike interesting. At a recent dinner held by a branch of the Medico-Political Union, which is an association of medical men contemplating the transformation of medical organisation into a trade-union, Dr. E. H. STANCOMB, a prominent member of the Union, said: "It is the miners' turn to-day, but it may be the doctors' turn to-morrow." He summarised the position taken up by the Medico-Political Union when called on to defend the institution of a medical strike in circumstances where professional protest has remained vain, assuming that this plight had arrived in respect of certain panel regulations. He contended that a medical strike would be against the Government in respect of the terms and conditions of service, but that no sick person would suffer, and that the strength of the strike would lie in the fact that there could be no blacklegs, as no person could, on the strength of a few weeks of intensive culture, possibly take the place of a professionally trained medical man. Two points arise from this presentation of the case for the establishment of a medical trade-union, and in the consideration of these it is not necessary to make any allusion to ideals of conduct. Ideals of conduct must show their influence personally and are thus removed from the sphere of any occupational organisation. First, a solidarity of opinion among medical men is assumed which no one believes would ever occur. Granted that a strike of medical men could not be broken by blacklegs from without, it is practically certain that it would be broken immediately from within. There could be no need for any Government, resisting a medical strike, to hastily call in the services of unqualified medical men. Within any form of medical union that is conceivable there would be immediate dissentients from the policy of withholding medical service; and, still excluding ideals of conduct from our thoughts, one reason for this is that medicine is not a homogeneous service in which common conditions prevail with all workers. Secondly, in what manner could any medical strike be directed against the Government unless it was primarily directed against the sick and suffering? A middle stage of the operations in a medical strike appears to be omitted from discussion in the arguments of those who desire to see a medical trade-union arrive. It is in this stage that the full force of public opinion would be ranged against the medical profession.

That the medical profession, unable to put the necessary pressure upon a Government, could reduce the public to such a position of need that the voice of a medical trade-union would become paramount, is a sequence of events which we do not believe could ever occur. It is for that reason that we have been unable to support the views of those who are attempting to transform the medical profession into a trade-union, and it is needless to look for others. The extreme weapon of a trade-union is a strike. No medical union that we can imagine would be able to use that weapon with the efficiency that comes from common agreement.

ENTRANCE BOARD REGULATIONS FOR SCOTTISH UNIVERSITIES.—New regulations governing entrance to the Scottish Universities were recently issued by the Entrance Board. The object of the new regulations is to unify the requirements hitherto insisted on for admission to graduation courses in the different faculties, and for this purpose to accept certain group certificates of the Scottish Education Department. The certificate must attest proficiency in four subjects, one being English, in which, as in two of the other three, the higher-grade standard must be reached. The marked departures from the present system are: (1) Neither Latin nor Greek is to be a compulsory subject; (2) mathematics is no longer to be a compulsory subject; (3) art, music, economics, &c., are now recognised as alternative subjects. At its meeting on March 28th the University Court of Aberdeen, having received communications on the subject from the Senatus, including reports from the faculties and from the General Council through its Business Committee, resolved to dissent from the regulations. At a meeting of the University of St. Andrews General Council it was agreed to join with the Aberdeen and Edinburgh University Courts in dissenting from the new regulations. The Courts' objection appeared to be that it is proposed to institute a common test for admission to all faculties, and this was considered to be impracticable.

Annotations.

"Ne quid nimis."

A SMALL BASTARDY BILL.

THE Bastardy Bill to be introduced by Captain G. E. W. Bowyer in the House of Commons on April 29th embodies what remained of Mr. Neville Chamberlain's "Children of Unmarried Parents" Bill after the latter emerged from Committee stage. It proposes to appoint the clerk to the justices (or, in London, the chief clerk of a metropolitan police court) as collecting officer under the Affiliation Orders Act of 1914. For some time past it has been difficult to induce any worthy person to undertake this duty, the importance of which will be much enhanced by the much larger payment which, if the Bill becomes law, may be levied on the putative father. It is further proposed that any illegitimate child whose father and mother shall have subsequently intermarried shall thereby, and as from the date of such marriage, be deemed for all purposes legitimate. The National Council for the Unmarried Mother and her Child, which is promoting the Bill, believes that although it does not go very far—care has been taken to ensure a measure of general agreement—lives will be saved thereby and the existence of the unfortunate child who is born out of wedlock deprived of some of its terrors. As such it will command the cordial support of the medical profession.

THE TRAINING OF THE HOSPITAL ALMONER.

IT is encouraging to find from the report of the Hospital Almoners' Council for the year ended 1920 that in the midst of much that is disappointing in voluntary hospital work nowadays, the Council has succeeded in overcoming many of the difficulties encountered during the war. The Council has a high ideal of its functions, and has set a standard of training which is no light one for the student. Candidates are expected to have had a liberal education, as far as possible up to the university standard, before embarking on the course of training; they should also be women with a wide outlook, broad sympathies, and a genuine interest in the social problems of the day, for, as the report points out, the work of an almoner necessarily implies very considerable interference in the lives of others, and success will depend largely on the spirit of sympathy and comradeship with which the work is carried out. The almoner's departments of the voluntary hospitals must share in the challenge of the modern situation. A considerable part of this challenge is to be found in the new attitude of Labour towards social amelioration, and the "charity" of Dickens's day belongs to a sentimental past. But the most important part of the challenge for the moment is the financial question. Hospitals are seeking to augment their incomes by means of payments from patients, and this policy will be reflected in the increased importance of the almoner. In some cases the payments take the form of a fixed sum paid for each attendance in the out-patient department or for each week's residence in the wards, the latter often estimated by the hospital as the amount to which the family exchequer is lightened by the absence of one of its members in hospital; in others the payments are assessed on a voluntary basis according to the patient's means. In either case, but perhaps more in the latter than in the former, added responsibility and need for tact and sympathetic insight are required of the almoner, who knows the social conditions of the patients in her district. Furthermore, everybody concerned with the treatment of patients in our voluntary hospitals is extremely anxious that money difficulties alone shall not prevent patients who are acutely ill from getting immediate attention, irrespective of their financial position. If rules and regulations as to payments have to be set aside—and it is the hospital's pride that they possess less of that much abused commodity known as red tape than almost any other British institution—the almoner alone knows the facts on which such decisions have to be made. And when we add to these questions the difficulties which occur daily with regard to ex-Service men and pensions, tuberculous persons and sanatorium benefit, lying-in women and maternity benefit, we are not surprised that a high standard of training is required of the almoner. We are also not altogether astonished that in some hospitals, at any rate, the new situation has proved almost unsurmountable. There is a real danger that the almoner's department may become a registration department where card indexes and account books are accurately kept and the human element is allowed to die out. If the mere registration of patients' payments and pension or grants to the hospitals are allowed to fill the major portion of the almoner's time we must not be surprised if we fail to get the right type of woman for the work.

The supply of trained almoners has hitherto barely kept pace with the demand. The Hospital Almoners' Council course of training extends over a period of two years, during which time the candidate is earning no salary. In addition there is a fee of 40 guineas for the course. This expenditure compares favourably with the cost of training for other professions followed by women, but it is probably one of the reasons why the supply of candidates has been limited in the past. The curriculum of the Council is divided into three parts: (1) three months' whole-time work in an office of the Charity Organisation Society; (2) nine months' (three terms) study under the Ratan Tata Foundation of Social Science and Administration of the University of London, including lectures on social subjects, elementary hygiene, and physiology; (3) 12 months' training in the almoners' department of a hospital training centre. As the Ratan Tata Foundation courses begin at Michaelmas, and as the three months' training with the Charity Organisation Society must precede this, it is necessary for the student to begin her training not later than midsummer.

Arrangements have now been made with some of the provincial universities (Glasgow, Leeds, Liverpool, and Durham) whereby students can take courses of study in these universities equivalent to those of the Ratan Tata Foundation in London. We should like to see this privilege extended not only to other universities but to some of the other branches of study. A practical insight into social conditions in a South Wales mining village or a Lancashire cotton town would widen a student's outlook immeasurably. Perhaps the time may come also when it may be possible for some students, at any rate, to study social conditions in industrial centres abroad.

In conclusion, we should like to hazard the hope that financial assistance, in some such form as a bursary or scholarship, may be forthcoming for training for this valuable new weapon in the armoury of medical sociology. It will be a thousand pities if promising students are lost to this work through lack of means.

LIPOMA OF THE SUCKING-PAD.

ACCORDING to Dr. Angus L. Cameron,[1] Teaching Fellow in Surgery of the University of Michigan Medical School, the corpus adiposum buccæ or sucking-pad was first described by Gedani in 1725, though Heister is usually credited for the first description in his *Compendium Anatomicum* published in 1732. The sucking-pad is a circumscribed mass of adipose tissue which lies in the cheek, partially wedged between the masseter and buccinator muscles and covered externally by the superficial fascia of the face and the zygomatic muscle, and connected posteriorly by a stalk with a much larger mass of fat which is known as the corpus adiposum malæ. Scammon, who examined the bodies of 42 individuals whose ages ranged from 20 to 60, found the sucking-pad well developed in 34, and in two well developed on one side and practically absent on the other. No relation was observed between the size of the sucking-pad and the age of the individual, nor was its size apparently affected by extreme emaciation. Dr. Cameron has collected 15 cases of tumour of the corpus adiposum buccæ from the literature published since 1848, exclusive of a personal case. Only three of the 15 cases were congenital, the ages of the remaining cases ranging from 10 to 62 years. Six of the patients were males, seven females, and in two the sex was not given. The right side of the face was involved in nine cases, the left in three, and in three the side was not stated. The size of the tumour varied between that of a large chestnut and that of a man's fist. Dr. Cameron's own case occurred in a boy, aged 14, who had had a facial tumour as long as he could remember, though it had only begun to increase in size for the last two years. It was soft, bilobulated, painless, and freely movable under the skin. A distinct sense of fluctuation was observed on external palpation, but the tumour was found to be solid on palpation from the oral cavity. A diagnosis of lipoma of the corpus adiposum buccæ was made and confirmed by operation, when a tumour weighing 36 g. was removed by a small incision in the mucous membrane. It shelled out easily except for the stalk connecting it with the corpus adiposum malæ, which had to be severed.

LIFE AFTER DEATH.

Sir Arthur Conan Doyle gave three lectures at the Queen's Hall, London, recently on "Death and the Hereafter," in which he demonstrated different aspects of spiritualism, giving the results obtained by psychical research. In his first lecture he described the investigations of Professor Crawfurd, of Belfast, who has written a book on ectoplasm or psychoplasm—the substance which, it is suggested, emanates from some mediums, and he quoted Thomas Vaughan, the seventeenth century alchemist and poet, in support of the recent observations on the building up of spirit forms. Vaughan, who appears to have derived inspiration from Cornelius Agrippa, described "the first visible receptacle wherein the spiritual things are consecrated, ... a viscous mass impregnated with all powers celestial and terrestrial; ...... it may be seen with the eyes and felt with the hands; ...... it alters every moment; ...... it is almost animal; it is the mother of all things; ...... it is a thick water which is dry and wets not the hands, a most delicate substance, and tender; ...... the least violence destroys it, even the vibration of light." Such a substance seems to be what we are asked to believe can be materialised and dematerialised by mediums.

Sir Arthur Conan Doyle's attitude towards his audience, as befitting a medical man, was not pontifical or dogmatic; it was that of an investigator who felt bound to pass on information which he had obtained and to relate what he had actually experienced. The experiments conducted with a medium called Eva in association with Madame Bisson, and recorded by Dr. Schrenck Notzing,[1] were described, and the lecturer told how he had actually seen and touched the mysterious substance emanating from mediums. In the second lecture stress was laid on the religious argument with spiritualism, and the lecturer deplored the fact that the Church had rebuffed investigators, instead of working with them as allies, to prove the existence of a life after death, and to confute materialists. He showed that the Fathers of the Church recorded fully spiritual phenomena, in the days when each church was ordered to have three discreet women, one with the gift of healing and two with spiritual gifts, quoting St. Augustine, Origen, Tertullian, and Jerome as describing occurrences similar to those found in the publications of the Society for Pyschical Research. Further, he claimed that St. Paul's list of spiritual gifts (I. Corinthians, xii., 8–10) is an exact description of the powers of mediums, clairvoyants, and clairaudients. He added that in his view there were no such things as miracles, but that everything is done by law, our failure to understand being due to conflict between old knowledge and knowledge later acquired.

---

[1] Journal of the American Medical Association, March 19th, 1921.

[1] THE LANCET, April 16th, p. 809.

The third evening was taken up with a display of spirit photographs. Certain of these showed mediums with masses of viscous-looking ectoplasm issuing from their bodies, and these masses, the lecturer stated, could not be detached without doing harm to the medium, as at the end of the trance it was reintegrated into their bodies. But he said that a small portion had been taken from the medium Eva and sent to analysts, who had decided that it had all the constituents of the human body. Certain obvious reflections in this connexion will have occurred to Sir Arthur Conan Doyle; he must know that before members of his own profession will pay heed to such "evidence" of life after death they will require proof that every step in this analysis has been undertaken with precautions against fraud and error.

ERYTHRŒDEMA.

IN 1914 Dr. H. Swift, of Adelaide, described at the Australasian Medical Congress a peculiar group of symptoms characterised by redness and swelling of the hands and feet, which he had observed in children. He termed it "erythœdema," but did not regard the word as satisfactory as the swelling did not pit on pressure. Comment was subsequently made upon these cases in our columns.[1] In the *Medical Journal of Australia* of Feb. 19th last Dr. A. J. Wood has published an important paper on the subject. He states that he has frequently seen such cases in Melbourne during the last 30 years, and that before his time Dr. W. Snowball, of the Children's Hospital, recognised the complaint, and spoke of it as "raw beef hands and feet." In Sydney the condition has also long been identified and spoken of by Mr. C. B. Clubbe and others as "the pink disease." Dr. Wood has now notes of 40 cases. Of the ætiology and pathology nothing is known. The majority of Dr. Wood's patients were between the ages of 8 and 18 months, but children at the breast as young as 3½ months and children as old as 3½ years have been attacked. The symptoms when well developed are most characteristic. The child is brought with the head bent down, generally into its mother's chest, or frowning with half-closed eyes, as though it dreaded the light. Usually it is whining and fretful. Some patients are restless, scratching at the feet or pulling at the hair and ears. If placed on the floor they bend forward so that the head almost touches the feet. They do not smile, and resent any attempt to amuse them. In some cases the red swollen appearance of the hands is an early and pathognomonic symptom. The children are worn out from want of sleep, and in distress from intolerable irritation of the skin of the body, hands, and feet. In young infants the earliest symptoms are fretfulness, insomnia, and disinclination for breast or bottle. After a week or two they may perspire freely, and a profuse irritable sweat rash appears. A little later (two or three weeks), or as late as four or five months after the onset of the fretfulness, the redness of the hands and feet appears. Muscular wasting is an early symptom. Stomatitis is common, and photophobia is very frequent. The itching leads to scratching, which may cause breaches of the skin, to be followed by ulceration. The redness of the hands and feet is accompanied by icy coldness to touch, and small vesicles may form. Loss of finger- and toe-nails is not rare. The axillary and inguinal glands may be enlarged. The rectal temperature is generally about 100° F., but is higher when complications, such as broncho-pneumonia, occur. Loss of weight takes place, though the food seems to be well digested. The urine is scanty. The first evidence of improvement is return of sleep and gain in weight. The prognosis is good, but the duration varies from three months to a year. Five deaths have occurred in 91 cases, but in only one could it be shown that death was not due to the complication of broncho-pneumonia. The treatment consists in sending the child to the country and leaving it as long as possible in the open air. For the sweating and irritability of the skin great relief is afforded by rubbing the whole body at least twice a day with methylated spirit and dusting with zinc and starch powder. For underwear a loose silk garment is preferable. For the irritable fingers and toes painting daily with tincture of iodine is satisfactory. If this seems too strong an application it may be diluted with an equal part of methylated spirit. Drugs do not seem to be of much use. For the insomnia trional, chloral, bromide, and opium have been given. Liq. opii sed. has been employed without relief. Sleeping in the open air in the country has succeeded when every form of hypnotic has been pushed in the city without effect. When methylated spirit or iodine has failed to relieve the itching it may be necessary to apply cardboard splints to the arms to prevent deep scratching.

NON-TUBERCULOUS APICAL DISEASE.

Dr. G. Liebermeister,[1] of Düren, reports having recently seen 15 cases following influenza in which the clinical appearances closely resembled tuberculosis of the apex. No tubercle bacilli, however, were found in the sputum, Pirquet's reaction was negative, and no reaction followed injections of 0·1 to 10 mg. of tuberculin. In 7 of the cases, indeed, the doses were increased to 200 mg. old tuberculin and 2000 mg. of bacillary emulsion without any reaction. He therefore considers that a tuberculous ætiology could be excluded with a fair degree of certainty. Fourteen of the cases recovered, although in some of the patients the apical signs were very persistent and it was many weeks before they finally disappeared. In the one fatal case severe hæmoptysis occurred, but no tubercle bacilli were found in the sputum in spite of repeated careful examinations, and the diagnosis of influenzal broncho-pneumonia was confirmed by the autopsy, at which no evidence of tuberculosis could be discovered. Dr. Liebermeister concludes by saying that it is most important at the present time, when influenza is so prevalent, to make an exact ætiological diagnosis in cases of apical disease of the lung, so that tuberculosis should be recognised and treated as early as possible and so that, on the other hand, the diagnosis of tuberculosis should not be made in the non-tuberculous.

HOME AMBULANCE SERVICE.

AMONG the problems calling for anxious consideration during a period of national emergency are those that concern the maintenance of hospital supplies, the provision of means to secure the transport of the sick to hospital from outlying areas, and the demands that may arise for the removal of the injured in any disturbances that may take place. Existing circumstances have afforded proof of the value of the Home Ambulance Service—one of the peace activities of the Joint Council of the Order of St. John and the British Red Cross Society. Under this scheme there are approximately 300 ambulance stations established in the country under the administration of county directors. Although these motor ambulances are exempt from the payment of licence duty on condition that they are used solely for the transport of the sick, it was felt that under the recent conditions the scope of their work must be extended if necessity arose. Thus, after consultation with the Ministry of Transport, instructions were issued to county directors that if they were called upon for the purpose of helping to maintain the essential supplies of the hospitals and convalescent homes in the country, the fullest possible use might be made of them for that purpose so long as the Ministry of Transport's special permission lasted. A day or two later, when military plans for safeguarding public interests developed, it became evident that an organisation having ambulances distributed throughout the country would be of invaluable service should disturbances occur, and, at the request of the War Office, county directors were further instructed that arrangements should be made so that, by coördination of the work of the ambulance stations, every possible assistance should be given to the authorities in dealing with casualties, while at the same time a minimum of dislocation should be caused to the hospital services and the normal work for the sick. It is even more necessary, of course, to maintain the independence of the Red Cross at times of civil disturbances than during war with a foreign State, and this was recognised by the military authorities, who issued orders that the ambulances should remain entirely under the control of the county directors and should not be driven by enlisted men. Similar arrangements proved entirely satisfactory during the Luton riots in July, 1919, when a large number of casualties were picked up by the Home Service Ambulance.

---

[1] THE LANCET, 1918, i., 611.

[1] Deutsche medizinische Wochenschrift, March 10th, 1921.

The normal work of the Service continues to give evidence of its value as a unit of the forces fighting disease, the latest report showing that 46,294 cases have been carried in the ambulances since the establishment of the Service less than two years ago.

CREEPING ERUPTION.

ACCORDING to Dr. Joseph Victor Klauder and Dr. Sigmund S. Greenbaum,[1] of Philadelphia, who report a case in a girl aged 6 years, creeping eruption, or larva migrans, which was first described by Lee in 1874, is a relatively rare disease in the United States, where only 18 cases have been recorded. The disease is commonest in Russia, and is also prevalent in the Shetland Islands and in Norway, as well as among Arabian children, whose mothers are said by Lee to burn the part affected with a hot wire. The eruption is due to a larva which is generally regarded by entomologists as the *Gastrophilus hæmorrhoidalis* of the horse. This organism measures from 1 to 1·5 mm. in width, possesses ten segments, and has hooklets which are more prominent at the cephalic end. Two suckers are present at the head end and two club like processes at the tail end. There are two tubes in the interior of the organism. The disease is most frequent in children. The parts most commonly affected are the hands or lower parts of the forearms, the feet, and lower parts of the legs. In exceptional cases the face, buttocks, genitalia, and trunk are involved. The characteristic lesion is a burrow, which is a raised erythematous linear lesion, serpiginous, and at times circinate in outline. The lesion is most distinct at the extending portion, and tends to disappear at the older and traversed part. Sometimes the burrow is composed of linear vesicles. On diascopy the larva is seen as a black speck at the advancing end of the burrow, whose rate of progress varies from a fraction of an inch to seven inches in the 24 hours. In most of the recorded cases only a single burrow was found, but in the present writers' case there were five separate and disconnected burrows. The duration of the disease is variable; not uncommonly it lasts for some months. Unless secondary infection occurs, there is little local reaction to the presence of the parasite. Histological examination shows that the burrow is present in the upper part of the epidermis between the stratum corneum and the rete Malpighii. The eruption is readily amenable to treatment by local applications of nitric acid, phenol, tincture of iodine, chloroform, and 2 per cent. salicylic acid in collodion.

BELGIAN METHODS OF ANÆSTHESIA.

TWO new methods, or rather two modifications, in recognised methods of anæsthesia are reported from Belgium,[2] where they have been put to a preliminary test. The first is a method of general narcosis, using a mixture of equal volumes of chloroform and ether plus half a volume of ethyl chloride. One and a quarter hours before the administration of this mixture a subcutaneous injection is given containing dionin and heroin, 0·005 g. of each; morphine, 0·01 g.; hyoscine hydrobrom., 0·0001 g. The dose is larger in muscular or alcoholic subjects. It is claimed that anæsthesia so induced is free from anxiety both to patient and operator. The amount of chloroform necessary is so small that there is no danger of syncope or delayed poisoning. The hyoscine removes "the harmful brake resulting from stimulation of the vagus." The pulse remains strong and regular throughout the whole anæsthesia. The patient breathes deeply and the colour is good. Heroin lowers the excitability of the lung surface, increases the ventilation without increasing the respiration-rate, and diminishes the "chloroform appetite." The dionin and morphine relieve the patient of anxiety and aid in establishing gradually the state of narcosis. The method was devised by Dr. Le Clerc-Dandvy. It is used only at ages over 17 years. Dr. Albert Govaerts, of Brussels, gives a list of 14 operations in which this method was used. Anæsthesia lasted from 45 minutes to 1½ hours. The amount of chloroform required varied from 3·5 to 11 c.cm. In one case, however—an operation for nephrectomy on an alcoholic subject lasting 1 hour—50 c.cm. of the mixture, and therefore 20 c.cm. of chloroform, were necessary.

The second method consists in the substitution of 4 per cent. scurocaïne for stovaine in spinal anæsthesia. The technique is also modified. Dr. G. Spehl, the originator of this modification, uses a 10 c.cm. syringe. The injection is made in the first or second lumbar space. A small quantity, not more than 4–6 c.cm., of cerebro-spinal fluid is allowed to escape, the syringe containing 4–12 cg. of scurocaïne is adjusted, and the piston withdrawn to the 10 c.cm. mark. After an interval one-half of the resulting mixture is injected and the other half after a second interval. The head of the patient is kept flexed on the chest and is raised throughout. After the injection the patient lies on the back with head well raised and the table is tilted from the feet at 10° to the horizontal. Anæsthesia is complete in 10 minutes. When the injection is made in the first lumbar interspace anæsthesia extends up to the clavicles. Twenty-eight observations have given encouraging results, headache and vomiting occurring in five cases only. More complete data are promised for later publication.

FAMILIAL VARIATION IN RESISTANCE TO INFECTION.

AN extensive experiment on the effects of in-breeding of guinea-pigs has been in progress at the U.S. Bureau of Animal Industry at Washington since 1906. A number of pure in-bred families have been developed by persistent brother-sister matings, which show permanent differences in respect of colour-pattern, polydactyly, infant mortality, and weight. Dr. S. Wright, of Washington, and Dr. P. A. Lewis, of the Henry Phipps Institute in Philadelphia, give[1] a most interesting account of experiments which they have made on the resistance of these families to inoculated tuberculosis. The difference may be very marked. Thus, with intra-peritoneal inoculation all of family 32 were dead at the end of 25 days, when 60 per cent. of family 35 still survived; with subcutaneous dosing the whole of the animals from family 32 had perished in 47 days and only 30 per cent. of those from family 35. In crosses with other resistant families the most resistant family transmitted its resistance by either sex to the offspring of either sex, and the progeny were superior in resistance to the most resistant family itself. Resistance to this form of infection appears to be independent of other elements of vigour, such as weight, rate of growth, or size of litter. Apart from their inherent interest, these observations seem to be important from two more general points of view. In the first place, they furnish most favourable material on which to resume once more the hunt for the factors—anatomical, chemical, or what not—on which resistance depends. Dr. Lewis is inquiring into the relation between resistance to tubercle and resistance to other infections, into any discoverable differences in the constitutions and economics of the two sets of animals, their phagocytic and antibody mechanics, and his results will be awaited with much interest. In the second place, the observations emphasise the care and circumspection with which experiments must be interpreted by forcing on our notice a factor which has hardly been suspected before. A race of guinea-pigs which have the audacity to have no end-piece to their complement has lately been revealed, and it is evident that if quantitative inoculation experiments are to reach their highest accuracy they must be made on a genetically homogeneous population. Evident, too, that along these lines one may look for reconciliation between divergent sets of observations. Perhaps in future our experimental animals will have to be as guaranteed as our dyes and chemicals.

THE DIET OF THE WEANLING.

THE neglect of the general practitioner to make himself familiar with the principles of feeding advocated at infant welfare centres has been freely criticised in certain circles. But are there as yet any well-recognised principles, excepting the desirability of breast feeding till the ninth month, on which there is general agreement? And if there are not, is not the general practitioner justified in depending upon his own experience, rather than upon pronouncements which themselves are in question? The report of a meeting of the Society of Medical Officers of Maternity and Infant Welfare Centres in our present issue shows that there is little unanimity on the subject of the proper feeding of infants between 9 months and 5 years of age. The assumption that the bulk of the food supplied to babies should be cow's milk, of which large quantities should be consumed, appears on the evidence submitted to be founded on slender enough basis, though milk certainly seems a useful and palatable vehicle for fats and for water. The mother familiar to us all, who gives her baby just "a snack of what we eats ourselves," used to be held up to execration, and, indeed, in most middle-class circles would still be accounted blameworthy. But, according to one expert, the mother who, on being asked why she gave her infant a chop, said that it was because "he won't eat pork," was selecting the most suitable food by the most rational experimental method—that of trial and error. To select apparently healthy children, to ascertain as a matter of interest what they habitually eat and recommend those in charge to carry on, may be a reasonable method, but it does not lead us much further. Dr. Harold Waller admits that sick and weakly children cannot be brought back to health by the varied diet that may be suitable to maintain the robust child in vigorous development, and the question remains whether the healthy child flourishes in spite or because of its food. The diet recommended by Dr. J. Sim Wallace as prophylactic against carious teeth appears to have been welcomed by many medical officers, possibly because to follow definite rules is always some satisfaction when facing a difficult problem. But the view that good teeth depend on general conditions, on resistance to infection, and on proper development of the mouth and jaw promoted by nasal breathing, appears more convincing to us than does the mechanical cleansing theory. In the nursery, manners and habits other than dietetic are formed, and a child who is allowed to chew but not to swallow crusts, or one who is encouraged to discard and eject, to bite and tear and worry food will have much to unlearn if he or she is ever to be a pleasant table companion. Moreover, those who focus their attention on dental caries appear to think only in terms of masticatory power, whereas good digestive habits have also to be acquired. The question of bulk is important in connexion with constipation, and the strength of the digestive juices in the young child remains to be ascertained and considered. The chronic epigastric malaise, for which no organic basis can be found, from which so many overworked members of our own and other professions suffer, may be traceable to dietetic indiscretions in early youth.

We know well that it is only the uninformed who are positive and that wheresoever a party of experts is gathered together there also is dissension. But we hope that this Society in the future may be in a position, as the result of its pooled experience, to tell us with some measure of authority what may be considered a dietetic indiscretion in an infant.

"THE FIGHT AGAINST DISEASE."

UNDER this broad title appears the first number of a journal which is to replace the reports hitherto issued quarterly by the Research Defence Society to its members. It will be published six times a year by Macmillans, will cost only *6d.*, and will be placed on the tables of the chief public libraries. The design of the Society appears to be the provision of accredited abstracts and reviews of recent research work in a form intelligible to the lay public, a function corresponding to that subserved by the Medical Research Council to the profession. Since nearly all modern developments in medicine have an experimental basis, the alteration will involve but little change in the character of the publications issued by the society, which will now, however, be made available to a much larger circle of readers. At present the public greedily consumes whatever diet—sometimes unnecessarily meagre, too often indigestible and excessively spiced—it is offered on medical subjects; a periodical giving reliable and simple accounts of recent advances should have success, though it cannot be sure of it. Though the days of sharp fighting for the rights of experimental work are practically over, medical research has other enemies besides the fanatics who would shackle it by force, and in the times of national penury ahead may have to be protected from starvation. The first number of the new journal reviews recent work on protection against tuberculosis and on Malta fever, and comments on the hospital stalls at the Efficiency Exhibition, outlining a constructive scheme for a permanent health exhibition under the auspices of the Ministry of Health. Annotated extracts from lectures recently delivered by Sir Charters Symonds[1] and Professor F. Hobday[2] show the beneficial potentialities of the comparative study of medicine and surgery not only for man but for animals. In the short obituary notices of Lord Moulton and Sir Felix Semon, which complete the number, the following words, spoken by Lord Moulton in 1907, show that the new journal is a natural development of the policy which has been maintained by the Society since its inception:—

> "The advance of science takes the workers in science more and more beyond the ken of the ordinary public, and their work grows to be a little understood and much misunderstood; and I have felt that the need would come for interpreters between those who are carrying on scientific research and the public in order to explain and justify their work."

The need for interpreters is no less great to-day.

UNDER the auspices of the Institute of Pathology and Research at St. Mary's Hospital a course of lectures on Pathological Research in its Relation to Medicine will be given in the lecture-room of the Bacteriological Department in the coming session at 4.30 P.M. on Thursdays. Among those taking part in the course are Sir James Mackenzie, F.R.S., Professor W. Bulloch, F.R.S., Professor Georges Dreyer, F.R.S., Dr. Leonard Hill, F.R.S., Dr. H. H. Dale, F.R.S., and Dr. J. A. Murray. The principal of the institute, Sir Almroth Wright, F.R.S., will give the introductory lecture on April 28th, taking as his subject *Acidosis and Acidæmia, with Special Reference to Scurvy and Shock.* The lectures will be open to all members of the profession and to students.

MEDICINE IN SOVIET RUSSIA.

BY BORIS SOKOLOV,

PROFESSOR OF PROTOZOOLOGY AT THE UNIVERSITY OF PETROGRAD.

[Professor Boris Sokolov was engaged before 1914 in experimental work—notably cultures in vitro of cancer and sarcoma—in collaboration with Professor Metchnikov. During the war he served on the Russo-German front, and in 1917-18 was a member of the Central Committee of the Russian Red Cross and a Deputy to the Constituent Assembly; later he held a post in the Ministry of Education for North Russia. Arrested by the Communist Government for political reasons, he was for some time employed as doctor in the Boutirka Prison, Moscow; upon his release he was enabled to keep in touch with medical and scientific work under the Communist régime. Dr. Sokolov is the author of several medical and political works.]

Soviet Medical Organisation.

Before the Soviet organisation came into being there existed in Russia a series of social and semi-social relief institutions—Red Cross, Blue Cross, provincial councils, and city organisations—working more or less independently. The Soviet system is based upon rigid centralisation, and all existing groups have been placed under the control of the Department of Public Sanitation and Hygiene; the entire medical organisation of the country is now in the hands of the State, and the development of bureaucracy has resulted in slackness of administration. The committees which in 1918 were responsible for hospitals and clinics have ceased to exist, having been replaced by commissaries, who act as inspectors and are all members of the Communist party. These commissaries are often chosen from the junior medical staffs, being appointed by political chiefs who know little of their qualifications; their power is absolute, and frequent conflicts with the hospital doctors resulted at first, although the situation is now becoming rather easier. The head of the Department of Sanitation and Hygiene is Dr. Semasko, a cultured and humane member of the Communist party, who lived for many years in Paris; his assistant, Dr. Salonev, is not so acceptable to members of the medical profession.

Condition of Medical Science in Soviet Russia.

It is exceedingly difficult to gain a clear impression of Russian medical science during the past few years, mainly owing to the almost complete extinction of medical journals. The *Russian Doctor* and others have ceased to appear, owing to paper shortage and various technical difficulties; publications relating to the work of private institutions, and those dealing with experimental medicine, bacteriology, &c., have suffered particularly. Since 1919 one State periodical, *Scientific Medicine*, has been edited by a literary and scientific group at Petrograd, and six smaller publications have struggled on for two years. Economic conditions generally, shortage of heat for laboratories, lack of animals for experimental purposes, &c., have paralysed scientific activity; the Institute of Experimental Science in Petrograd has completely ceased to function, and those laboratories which are still open can only carry on a minimum of work. Among the latter is that of Professor Pavlov, who in 1920 published an article dealing with the physiology of the large hemisphere. The Institute of Experimental Medicine is still working, but many bacteriological laboratories have been closed. Clinics which in 1918 were noted for research work are now only able to deal with the sick; the only sphere in which research has still been possible is that of epidemic diseases. Typhus exanthematicus has been carefully studied, especially by Professor Ilatogorov at the Medical Institute, Petrograd; by Professor Marzenevsky at the State Institute of Sanitation, Moscow; and by Professor Pletnov at Moscow. The fact that all joint meetings of medical and bacteriological societies have recently devoted their time to the study of typhus sufficiently indicates the present importance of the problem in Russia. Among reports presented at conferences in 1920 the following were of particular interest:—Professor Zarassevitch, "The Present Position of Epidemics"; Dr. Nikitine, "Peculiarities in the Course of Infectious Diseases"; Professor Lionbarsky, "Immunity and Insufficient Nourishment"; Professor Pletnoff, "Pathogeny of Typhus"; Dr. Koutune, "Coagulation of Blood in Typhus"; Dr. Vorobiev, "Viscosity of Blood in Typhus"; Professor Levanov, "Blood Changes in Typhus."

Experimental Research into Typhus.

The following are details of laboratory researches into the questions of typhus and other epidemic diseases. These researches were based on vaccination with blood serum; in this connexion I would mention an article[1] by Professor Liotropov. This method of vaccination was used simultaneously by Professor Ilatogorov and Dr. Svachetzev in Petrograd, and Drs. Marzenevsky and Rosenthal at Moscow. Typhus patients' blood defibrinated and citrated was used as vaccine matter (18 c.cm. blood + 2 c.cm. citrate of soda at 2 per cent.). At Moscow Rosenthal's experiments are done in the same way. Marzenevsky used blood serum of typhus patients. The blood mixture used was rendered harmless by heating at 58° C., danger of infection at the time of vaccination being thus removed. In order to give to this vaccine a homogeneous character blood serum from several patients was employed. Professor Ilatogorov's experiments were usually tried on his medical staff; he proved that infection occurred in less than 0·24 per cent. of those vaccinated. Professor Ilatogorov's principal conclusions gathered from his work on preventive vaccine for use against typhus are the following:—

(1) The blood of typhus patients can be used after from 5 to 10 days as an antigen. (2) Patient's blood rendered inactive and defibrinated is harmless when used for injections. (3) Susceptibility to the disease is apparent in one vaccinated person to every five unvaccinated. (4) Vaccination done three times gives the same result as a single vaccination. (5) The initial dose must not be inferior to 5 c.cm. of defibrinated blood. (6) The vaccine matter must be polyvalent.

Conclusions from Professor Ilatogorov's reports on vaccinotherapy in typhus are as follows:—

(1) The blood of typhus patients can be used after from five to ten days of illness as a curative vaccine matter; (2) in vaccinotherapy a quantity of 1–3 c.cm. of defibrinated and warmed blood is used in hypodermic injections, and is repeated from two to three times every 48 hours; (3) the results of vaccinotherapy are generally of a negative kind; (4) the serum of convalescent typhus patients (from 2–12 days after the fall of temperature) can be used as a curative mean; (5) in serotherapy the polyvalent serum is injected subcutaneously in quantities of from 15 to 30 c.cm.; (6) serotherapy gives most encouraging results.

Professor Marzenevsky uses for his experiments blood serum (taken from typhus patients), mixes it with an equal quantity of physiological serum which has been sterilised and heated at 58–60° C. during one hour. He made four injections of this mixture of 1, 2, 3, and 4 c.cm. respectively, making a total of 10 c.cm. of pure serum. These experiments were mostly carried out in the Botkine Hospital at Petrograd; and after experiments with antityphus serum according to Nicolle's method the doctors of that hospital came to the following conclusions, which were reported by N. A. Sokolov:—

> "The effect of vaccine matter upon the organism following this method gives unimportant results. Drs. Radzevitch and P. Triodine, in their work 'On the Serotherapeutics of Typhus,' are of opinion that curative vaccine matter obtained from horses gives no local reaction when injected with doses of 25–125 c.cm., and at the same time diminishes the coagulation period."

A report of special interest to epidemiologists is Dr. Schutzer's "Preventive Vaccine Matter for Use against Typhus by Means of Cultivation of the Proteus Bacillus," of which the principal conclusions are:—

(1) The proteus bacillus exists as a constant agent in typhus; (2) The vaccine matter of a killed cultivation of *Bacillus proteus* containing 250 millions of bacteria per c.cm. in a dose of 0·5 c.cm. creates a violent reaction in the organism.

Still more interesting is the work of Dr. I. Sokolov, because it has a certain practical value in the differential diagnosis of typhus by means of "hypostatic hyperæmia."[2] This writer has come to these conclusions:—

> (1) The skin in typhus reacts against venous stagnation; (2) this skin reaction is especially characteristic of exenthematic typhus; (3) in order to produce this "hypostatic hyperæmia" a tourniquet must be applied around the shoulders; (4) the skin in this illness reacts in forming petechiæ from 12 to 24 hours before the appearance of the rose rash.

Other Research Work.

Among other work on epidemics should be mentioned Professor Gamalé's "Volatile Vaccine Matter."[3] Compared with the other volatile vaccine matter of cholera, distillation of alkaline solution of cholera vibrios produces immunity about the second or third day instead of about the fourteenth. Besides, although not colloidal, these vaccines can be absorbed by the intestine. Gamalé concludes thus:—

> The volatile vaccines produce a real immunity. They are not homogeneous, but their action shows that successful vaccination can take place without either agglutination, precipitation, or formation of bacteriolysins.

Amongst works bearing on conditions under Soviet government those which deal with starvation must not be omitted.

Researches in this direction were mostly done (in the laboratory set apart for the physiology of nutrition in the State Institute of Sanitation at Moscow) by Professor Chaternikov and his assistants, but the interest of the results is more physiological than medical. Some of the work done, however, has a purely medical interest—e.g., Professor v. Dolganov's observations on detachment of the retina as a result of starvation.[4] He has traced the causation of this detachment by observation of a great number of cases.

Looking over the work done during 1919–20 with reference to tuberculosis and surgery, it must be admitted neither of these questions was much studied. The conditions under which medical men have lived have prevented them from undertaking researches of no direct practical value. Clinics and laboratories which are needed by the Government are given a big subsidy, but others are left with no means at their disposal; this is, perhaps, the explanation of the specialised nature of work done during the past two years.

Relations Between the Government and the Medical Profession.

The members of the medical profession are the only "intellectuals" whose work has not been interrupted by the communist revolution. They have maintained a neutral attitude in political matters, although anticommunist as a body; hence Dr. Semasko's principal advisers are Professors Zarrasevitch, Diatropov, and Koltzov, all of whom are well-known constitutional democrats—that is, members of a liberal party which was treated with particular severity by the communist government. Doctors in general feel themselves bound to maintain as far as possible the health of the immense population, of which the majority cannot be held responsible for the revolution or its consequences. Twenty-five per cent. of the profession have left Soviet Russia—57 of them are now living at Capri as refugees—but those who remain continue their work with energy and devotion. Professor Koltzov was recently imprisoned for six months for participating in a counter-revolutionary movement; Professor Pavlov was refused permission to leave the country, and an attempt to attach him to the communist party by means of an increased food ration failed; whilst a general expression of opposition to the Soviet power was made by the Medical Conference held at Moscow during August and September, 1920—after which Dr. Semasko, who was present, threatened drastic measures of control. But on the whole, and except for the lack of medical materials and foodstuffs, the medical organisation is up to date and nearly as good as that in force before the war—mainly because the responsible posts in medical affairs are still in the same hands. The communist doctors are very few in number, and most of them more or less inexperienced.

Position and Life of Medical Men.

The peculiar conditions of life under the Soviet administration, the continuous civil war, and the wide spread of epidemics, have made the position of medical men very difficult; their political neutrality resulted in many being shot by the Reds, and many others by the Whites. Numerous members of the medical profession are still imprisoned by the Soviets; but after three years of civil war Whites as well as Reds began to appreciate their work and respect their neutrality. Finally, when a doctor was taken prisoner by either side he was immediately required to serve in a professional capacity. The profession has suffered more from epidemics than from persecution or civil war. From Nov. 1st, 1917, till August 1st, 1920, cases of typhus alone were as follows: doctors, 520, with 95 deaths; assistants, 272, with 63 deaths; nurses, 3520, with 927 deaths. During the same period of time 47 per cent. of Petrograd doctors have died; and it would be difficult to find a single doctor or nurse who has not suffered from two or three attacks of continued fever of some form or other. In the spring of 1920 a general improvement of health was noted; Professor Tchistovitch expressed the opinion that by that time the entire population was practically immune. In six months the percentage of persons suffering from some epidemic disease decreased from about 30 per cent. to 10 and even 7 per cent.

Turning to the consideration of economic conditions: when the Soviet power was first established, the greatest strictness was observed in the matter of equalisation of wages, so that early in 1918 experienced doctors were earning little more than their assistants; the result of this state of affairs was that a large number of medical men gave up practice and attempted to earn a living outside their profession. Later, however, they were recruited by the Government and given better rates of payment; those in charge of epidemic diseases were allowed extra food rations, but in spite of all measures taken, the salaries of doctors and trained nurses are still insufficient. Assistant doctors are paid according to category 21, which allows them about 4000 roubles a month; trained nurses receive 2000 roubles; the insignificance of these sums will be apparent when it is realised that a pound of butter costs 5000 roubles. Only by attending private clients and by undertaking lay employment can the Russian doctor manage to live; the "bourgeois" client of pre-revolutionary days can no longer afford the services of a physician, and in many cases doctors treat "professional" clients free of charge. The new class of paying patients is drawn from the communist bureaucracy and the successful speculators. Professor Ov, the celebrated Petrograd gynæcologist, asked 100,000 roubles for a small operation performed upon the wife of Linoviev, a leading communist; and this sum is not at all extraordinary. The Government, fearing that private practice renders medical men too independent, introduced in September, 1920, a regulation whereby the number of private patients is limited; and no doctor may write more than 50 prescriptions for private clients per month. The use of prescription books with numbered pages has been made compulsory, and the measure has naturally caused a great deal of dissatisfaction amongst practitioners.

Condition of Hospitals and Clinics.

During my stay in Soviet Russia I visited a number of hospitals and clinics with the intention of discovering whether the condition of these institutions had altered for better or worse; in many hospitals improvements are to be seen, particularly as regards disinfection and sanitation. The constant presence of epidemic diseases has, of course, brought to light new methods of isolation in city hospitals. On the other hand, slack discipline is noticeable amongst the staffs of the civil hospitals. Patients are not uncommonly ill-treated, and delirious cases have even been beaten; and as the doctors have not full control little can be done to stop these abuses.

In August, 1920, I was very painfully impressed by the state of chaos in which I found the Central Infirmary at Moscow. There the rules concerning isolation were very badly kept, and diagnoses were so superficially made that cases of typhoid and cases of tuberculosis, for example, were to be found in the same ward. At that time I did not notice any great shortage of medicines or surgical apparatus in the large towns, but the provincial "zemstvo" hospitals were being closed for lack of staff and materials. The hospitals in Petrograd and Moscow still had quinine, aspirin, and anæsthetics, but judging from a talk I had with Dr. Semasko, and by figures which I saw, the reserves were then coming to an end. In August only a few kilogrammes of chloroform were left in Petrograd, and all morphia had already been used up. A salvarsan preparation was being sold, but was of bad quality. Surgical instruments were also running short. Figures given by the Department of Health and Sanitation showed that on May 1st, 1920, the allotment of beds was roughly as follows: epidemic cases—civil 250,000, military 250,000; other cases, 500,000.

Statistics of infectious diseases.—The statistics given are incomplete, for it is impossible to obtain accurate returns from the provinces, but the estimated number of cases of epidemic disease in Soviet Russia during the past three years stands at the appalling figure of 31,789,230. The average mortality was from 5 to 7 per cent. of that number. The diseases most in evidence were typhus exanthematicus, typhus recurrens, typhoid, cholera, influenza, and dysentery. Cholera broke out in the spring of 1918, there being 35,619 cases during the year; Petrograd, and then the Volga region, suffered most heavily, the mortality in the latter district rising to 60 per cent. The autumn of 1919 was marked by a recrudescence of cholera, but still more deaths were caused by typhus. It is impossible to give figures for the whole of Soviet Russia, as owing to shortage of personnel records were not kept in many provincial hospitals; but the recorded figures showed that typhus began in the summer of 1918, there being 4519 cases in October of that year, 7933 in November, and on July 1st, 1919, the figure stood at 1,299,202 (Siberia not included). From 400,000 to 420,000 persons died of the disease during 1918-20. In some places it was impossible to bury the dead except in communal graves, with no coffins or burial ceremonies; at Saratov a "week of the dead" was appointed, and the entire population had to take part in burying the bodies.

Influenza also broke out in 1918, there being 700,000 cases during the year, with a mortality-rate of 15 per cent. The later incidence of the disease was not so serious. At the same time typhus recurrens spread through large tracts of Central Russia, but in this connexion figures are not available. In the summer and autumn of 1920 epidemics seemed quieter, but there is no reason to suppose they will not break out again; the exhaustion of the populace and unhygienic conditions contribute to the likelihood of their doing so. The living conditions in the towns are particularly bad; overcrowding, and neglect of the most elementary rules of hygiene, are there associated with grave defects in water-supply and drainage.

The Government has brought out a series of posters, urging the population to fight lice as energetically as they have fought the middle classes. "Burn them, kill them, cover them with petrol, iron them!" is the wording of these posters.[*] Petrograd has in every epidemic suffered more than any other part of the country. Up till August, 1920, the total of cases of influenza and typhus taken together was 202,173.

Diseases in Soviet Russia.

A Russian medical man has humorously said that it is not true that Bolshevik rule brought nothing but evil to Russia, for a certain number of people who once suffered from obesity and chronic catarrhs are cured, and even feeling younger. It is an undoubted fact that many diseases have entirely disappeared as a result of the change brought about by the abolition of idleness. A Petrograd physician told me that of 300 of his patients only 9 suffered from dilatation of the heart caused by obesity; 5 of these were well-known communists and the other 4 profiteers. A new illness has, however, appeared in Petrograd as a result of the eating of badly-cooked wheat. Its symptoms are frequent pains in the right side of the abdomen, general weakness, dizziness, nausea, and distaste for food. Tuberculosis is spreading widely in the towns as a result of the entire lack of fats, and in Petrograd a tremendous increase of lung troubles has taken place. The infirmary at Moscow contained 12 per cent. of tuberculous cases in 1917, and now contains 37 per cent., the general condition of the country especially favouring infection of all kinds.

Bad food has brought about general exhaustion and various forms of anæmia, especially in the towns; the general ill-health is very striking to anyone newly arriving in Russia. Professor Ov has stated that 30 per cent. of women and girls are no longer menstruating because of anæmia and under-nourishment. A very large increase of miscarriages naturally results from present conditions; an assistant at the Gynæcological Institute at Petrograd told me that women are terrified at the thought of bearing a child, knowing perfectly well that if born alive it will in all probability shortly die.

The Government has abolished open prostitution and regulated brothels, but this evil has merely assumed a different character; there are now more prostitutes than before, although Petrograd doctors do not report any increase in venereal diseases.

Patients admitted to hospitals show, on the whole, more carelessness concerning their health, as they realise the difficulty of obtaining proper treatment.

Condition of Children in Soviet Russia.

The gravest effect of recent Russian history is apparent in the younger generation; such, at least, is the view of the "League for the Protection of Children," which is headed by Professor Zarassevitch. Parents are overworked and unable to bring up their children properly; the lack of control is having the most serious results; the actual destruction wrought by the revolution is nothing to the appalling moral degeneracy and criminality among children which now stands out as the foremost evil of modern Russia. At one hospital, where the number of children suffering from venereal disease used never to be higher than 15 per cent., 60 per cent. are now affected as compared with 40 per cent. of adults. Moreover, the children born during the past two or three years in Petrograd and Moscow are weak and ailing on account of under-nourishment. A newborn baby frequently weighs no more than 6 lb., the normal weight being 8 lb. The new generation is being overcome by eczema, anæmia, and rickets, and every doctor in private practice numbers more children than adults amongst his patients.

Those in authority have at least realised the seriousness of the position, and children's hospitals and sanatoriums have been instituted, some by the Government, others by "intellectuals" acting with Government approval. Many of the measures taken have, however, already come too late. The Government consider the time has come for the nationalisation of children; it remains to be seen whether they will dare to put such a measure into operation.

Conclusion.

In this short account of the medical situation in Soviet Russia I have had one aim only, to bring to light, as impartially as possible, the actual state of affairs; the attempt has naturally been painful and the degree of objectivity attained is, perhaps, only relative.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

The Position of Poor-law Medical Officers.

THE position of Poor-law medical officers in certain parts of the country becomes every day more difficult. In unions in which the guardians have repudiated the authority of the Local Government Board the Government grants, from which a portion of the Poor-law salaries was paid, have been withheld. At the same time the Local Government Board still claims the right to dismiss medical officers or to mulct them in costs by process of mandamus if they fail to send the usual returns to the Board. On the other hand, the guardians have the power of withholding a medical officer's salary should he, in disobedience to their orders, send returns to the Local Government Board. The medical officers whose only desire is to continue to do their professional work without interference, find they cannot hope to serve two masters, and are actually performing their usual duties without receiving any salary. Last week a new factor further complicated the position. Several local authorities received a circular letter, purporting to come from the Local Government Department of Dail Earann, containing the following warning:—

> "Where a local authority has by resolution declared allegiance to Dail Earann and has severed all relations with the English Local Government Board, instructing its officials to cease communication with that institution, any such communication, written or verbal, direct or indirect, with that institution or any of its officials, or any person acting on behalf of any of its officials, will be deemed a treasonable practice and dealt with accordingly."

I do not pretend to interpret the threat in the closing words of this warning, but to a man living in a country district in Ireland it is not to be taken lightly. Last week the Council of the Irish Medical Association drew the attention of the Local Government Board to the danger to which they were exposing Poor-law medical officers for the performance of what is, under present conditions, a mere formality.

April 17th.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Statistics of the University Term.

THE following are instructive items from the prospectus for the coming summer term (April 15th to July 15th). Four hundred and seventy-two classes will be held for ordinary students and post-graduates, as against 448 held last summer term. The number of men engaged in this work is 24 ordinary professors, 135 extraordinary professors, and 157 assistants. These figures differ only slightly from those of the last winter term. Two members of the Senate of the Medical Faculty, the professor of medical chemistry and the director of the first clinic for obstetrics and gynæcology, have not yet been appointed. The published figures show that the number of ordinary medical students is declining somewhat; the present total is 4282, as against 4529 a year ago; female students number 578, as against 600 last year. It is believed that later figures will show a further drop because of the increased fees payable by foreign students in compliance with the demand made by the Rockefeller Foundation,[1] to which I have already alluded.

American Food Supplies for Students and Scientists.

The American Relief Committee, which has fought starvation by supplying a free daily meal to about 200,000 children in Austria alone, has now extended the scope of its work to include assistance of the so-called "mensæ." These institutes provide a midday dinner for university students in Vienna, but for many months this meal has been very scanty owing to lack of funds. The Relief Committee has now made arrangements to supply sufficient food for an additional daily meal of the food value of 1000 calories. It will consist of rice, cocoa, butter or fat, sugar, flour, beans, and peas; all students will be entitled to apply for it, with no distinction of race, creed, or stage of study. The professors and lecturers have also a special mensa of their own, where they obtain a good meal at a nominal cost—hardly enough to cover part of the rent. It is intended to compare the weights of the students before beginning the additional meals, and after partaking of them for periods of 4, 8, and 12 weeks.

Twenty-fifth Anniversary of the Discovery of the Rontgen Rays.

On March 18th the Medical Society of Vienna held a solemn meeting in honour of the twenty-fifth anniversary of Professor Rontgen's great discovery. A paper was read by Professor Lecher, the famous physicist, on "Physical Aspects of Rontgen's Discovery," in which he explained the use of X rays in ascertaining the number and inner construction of elements and their atoms. He mentioned the splendid work of the English scientist Moseley, who fell when very young in action at the Dardanelles.

A Peculiar Psychical Condition After Gas Poisoning.

At a recent meeting of the Medical Society of Vienna, Dr. Geistmann showed a patient in a peculiar condition produced by illuminative-gas poisoning. The condition was characterised by a complete loss of apperception, differentiation, and recognition of objects and occurrences of the outer world—a loss of the functions of thinking, reasoning, and judging, in short, of the higher psychical spheres altogether. The patient's behaviour permits of the assumption that the cortex cerebri, the centre of psychical activity, had completely ceased to function. He displayed an extreme degree of dementia; the very earliest reflex phenomena—echolalia and echopraxis, as seen in infants—were demonstrable in him. When any object was brought near his face he moved his lips as if to eat it, showing suppressive reflexes from the cortex to be entirely absent. He repeated mechanically, without understanding it, any word or sentence spoken to him, and every movement or gesture made before his eyes was at once imitated. His motorial condition reminded one of the primitive forms of movement seen in the lowest animals, although he had retained normal function of the bowels, kidneys, and vascular system. The case seems to be unique, and will be further reported upon later.

Reform of the Public Health Service.

The ever-increasing scope of preventive medicine necessitates a reform of the Vienna health service. A special committee has been appointed to draw up the outlines of the proposed reform. The following principles have been agreed upon, and will be recommended to the municipal authorities. All matters pertaining to public health will be centralised in the "Stadtphysicat," controlled by the ober-stadtphysicus (chief M.O.H.); the central office will contain several departments, each with two or more subdivisions, to deal with separate problems such as the following: general direction of sanitation of the city; standardisation of tariffs and schedules in employments; preparation of standard forms for health reports and statistics, milk distribution, and additional fat and sugar rations for diseased persons; control of municipal institutes of health; and instruction of the public health service. The hospitals, and hygiene, bacteriological, and chemical institutes are to be controlled by a special department. Public welfare work, child welfare, care of the tuberculous and the crippled (including war cripples) is to be centralised in another department, which will also deal with inspection of markets and of the sale of medicines. Coöperation with the State Board of Health, which deals with the corresponding work throughout the rest of the country, is, of course, expected, and it is hoped that the reorganisation of this important side of local government will result in permanent benefit both to the ratepayers and to the municipality.

April 14th.

The Services.

INDIAN MEDICAL SERVICE.

THE rates of pay and pension have been improved and *additional pensions granted for administrative officers* of the Indian Medical Service. A communiqué from the India Office says that the reforms will date from Jan. 1st, 1920, showing that the representations of the last 12 months have received a sympathetic hearing.

The position of the Indian Medical Service is well known to all our readers, and the difficulties need not be repeated here. Two Committees, one presided over by Sir Verney Lovett and one presided over by Lord Esher, have sent in valuable reports dealing with the anomalies of the Service, and recognising the political complications which have been introduced. The Service has for many years declined in popularity with the medical profession, and the recent constitutional changes in India have had a further depressing effect. *There has been a steadily increasing difficulty in* obtaining recruits of the right stamp, but the communiqué from the India Office may be taken as a step towards reform.

The terms upon which officers can enter the Service were set out in full in the last Students' Number of THE LANCET, and have since been repeated in our advertisement columns. They show a great improvement upon previous conditions, and ought to prove attractive.

ROYAL AIR FORCE NURSING SERVICE.

REGULATIONS regarding conditions of service in the Royal Air Force Nursing Service, which was established by Royal Warrant on Jan. 27th, 1921, have been issued. The Service consists of a matron-in-chief, matrons, senior sisters, sisters, and staff nurses. Candidates are required to join as staff nurses, and appointments, which are subject to a satisfactory probationary period of six months, are given to approved persons of British parentage, over 25 and under 35 years of age, who possess a certificate of training for at least three years at a large civil hospital in the United Kingdom.

Salaries.—The salaries of the various grades are as follows:—

Staff nurses: £60 per annum, rising by annual increments of £2 10*s.* to £65.

Sisters: £75 per annum, rising by annual increments of £5 to £85.

Senior sisters: £85 per annum, rising by annual increments of £10 to £95.

Matrons: £115 per annum, rising by annual increments of £10 to £185.

In addition, charge pay, not exceeding £45 per annum, is granted to matrons according to the magnitude of their charges, and a weekly allowance of 24*s.* 6*d.* to all members in lieu of board and washing. Furnished quarters, fuel, light, and attendance are normally provided, but where this is not the case an allowance in lieu is granted. An initial grant of £20 is made towards the cost of purchase of the prescribed uniform which members are required always to wear when on duty and when attending official or public entertainments, and an upkeep allowance of £5 for the second year and £10 for the third and subsequent years.

Retired pay.—Members of the Royal Air Force Nursing Service may retire at the age of 50 or after 20 years' service, and retirement is compulsory at the age of 55. Retired pay, based on service and rank, is issued up to the following maximum rates, which are subject to revision in five years' time:—Matrons, £170; sisters, £75; staff nurses, £55. Members employed in the Royal Air Force Temporary Nursing Service and previously employed in the Navy or Army Nursing Service may count the period of such service towards retired pay. A nurse with less than ten years' service will not be eligible for retired pay, but provision is made for the issue, under certain conditions, of retired pay and gratuities in the event of such service being terminated owing to disablement, sickness, or unfitness.

Full particulars of the Service and forms of application for appointment may be obtained from the Matron-in-Chief, Air Ministry, Kingsway, London, W.C. 2.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lieut. W. L. Coullie to be Surgeon Lieutenant-Commander.

Surg. Cmdrs. A. C. W. Newport, S. Roach, and G. D. Bateman to *Pembroke*, additional, temporary. Surg. Lieut.-Cmdrs. H. St. C. Colson and G. A. S. Hamilton to *Pembroke*, additional, temporary. Surg.-Lieuts. H. L. Pridham to *Pembroke*, additional, temporary; C. N. Ratcliffe to *[illegible]*, and A. G. Taylor to *Sandhurst*.

ROYAL ARMY MEDICAL CORPS.

Major W. E. C. Lunn relinquishes the acting rank of Lieutenant-Colonel.

Temp. Capt. C. H. Evans relinquishes his commission and retains the rank of Captain.

TERRITORIAL FORCE.

Major W. A. Thompson to be Lieutenant-Colonel and command 3rd Northumberland Field Ambulance.

Capt. G. C. E. Simpson to be Lieutenant-Colonel and command 2nd West Lancs Field Ambulance.

Capts. A. D. Kennedy, L. T. Whelan, L. A. Mackenzie, J. Turtle, S. J. Fielding, H. W. Symons, and J. Taylor to be Majors.

Major T. P. Cole (late R.A.M.C.) to be Captain, and relinquishes the rank of Major.

Major (acting Lieut.-Col.) L. C. V. Hardwicke relinquishes the acting rank of Lieutenant-Colonel on ceasing to be specially employed.

Capt. C. G. Teall (late R.A.M.C.) to be Lieutenant and relinquishes the rank of Captain.

Capts. A. W. A. Davies, W. H. Kerr (late R.A.M.C., S.R.), and H. V. Walsh (late R.A.M.C.) to be Captains.

Capt. L. T. Challenor vacates the appointment of D.A.D.M.S., 48th (South Midland) Division.

R. E. Pleasance (late Surg. Sub-Lieut., R.N.V.R.) to be Lieutenant.

Officers relinquishing their commissions: Major (Bt. Lieut.-Col.) B. M. H. Rogers and Major W. R. N. Smithard (granted the rank of Lieutenant-Colonel), Majors L. T. Whelan and J. Owen (retain the rank of Major), and Capt. W. E. Kingdon (retains the rank of Captain).

TERRITORIAL FORCE RESERVE.

Major G. F. Whyte, from General List, to be Lieutenant-Colonel.

ROYAL AIR FORCE.

Capt. G. W. J. Bousfield is transferred to the unemployed list.

INDIAN MEDICAL SERVICE.

Captains to be Majors: B. Gale, J. H. Horne, H. H. King, R. E. Flowerdew, J. G. B. Shand, A. J. Lee, C. H. Smith (Bt. Major), T. J. C. Evans, A. C. Anderson, D. G. Cooper, W. L. Forsyth, and G. T. Burke.

Lieut.-Col. R. Steen and Major M. J. Quirke retire from the Service.

The following relinquish their temporary commissions:—Temp. Captains: Amar Singh Dogra, Bantwal Shankar Rau, and Bankim Chandra Banerjee. And are granted the rank of Captain: Sant Singh Duggal, Ramakrishna Venkata Rajam, and Ram Chandra Bose.

URBAN VITAL STATISTICS.

(Week ended April 16th, 1921.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate population estimated at 18½ million persons, the annual rate of mortality, which had been 13·0, 13·0, and 12·5 in the three preceding weeks, was again 12·5 per 1000. In London, with a population of 4½ million persons, the death-rate was 12·4, or 1·0 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 3·4 in Ealing, 5·9 in Walthamstow, and 6·5 in Dudley, to 18·3 in Bath, 20·3 in Merthyr Tydfil, and 23·8 in Eastbourne. The principal epidemic diseases caused 241 deaths, which corresponded to an annual rate of 0·7 per 1000, and comprised 62 from diphtheria, 59 from infantile diarrhœa, 58 from whooping-cough, 50 from measles, 9 from scarlet fever, and 3 from enteric fever. Measles caused a death-rate of 1·0 in Sunderland, 1·6 in Newcastle-on-Tyne, and 2·9 in West Bromwich. The deaths from influenza, which had been 122, 130, and 97 in the three preceding weeks, rose to 111, and included 49 in London *and 5 each in Brighton and Liverpool. There were 3345 cases* of scarlet fever and 2543 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 3453 and 2626 respectively at the end of the previous week. During the week ended April 9th 6 cases of encephalitis lethargica were notified in the County of London, and comprised 2 in Hampstead, and 1 each in Chelsea, Hackney, Islington, and Stepney. The causes of 26 of the 4436 deaths in the 96 towns were uncertified, of which 10 were registered in Birmingham, and 2 each in London, Gillingham, Liverpool, and Warrington.

Scottish Towns.—In the 16 largest Scottish towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 15·3, 15·5, and 15·1 in the three preceding weeks, fell to 14·6 per 1000. The 328 deaths in Glasgow corresponded to an annual rate of 15·5 per 1000, and included 32 from whooping-cough, 6 from infantile diarrhœa, 5 each from scarlet fever and diphtheria, and 1 from measles. The 123 deaths in Edinburgh were equal to a rate of 14·4 per 1000, and included 10 from measles, 3 from whooping-cough, and 1 each from scarlet fever and diphtheria.

Irish Towns.—The 130 deaths in Dublin corresponded to an annual rate of 16·0, or 3·0 per 1000 below that recorded in the previous week, and included 4 from infantile diarrhœa, and 1 each from enteric fever, whooping-cough, and diphtheria. The 130 deaths in Belfast were equal to a rate of 16·1 per 1000, and included 7 from whooping-cough, 3 from infantile diarrhœa, and 1 from measles.

Correspondence.

"Audi alteram partem."

THE ULTIMATE SUFFERERS.

To the Editor of THE LANCET.

SIR,—The present crisis is hitting the mothers and babies very hard. At some of the centres I attend there is already a very marked difference in the appearance of both. It would be easy to pick out from about 30 mothers at one centre those whose husbands are out of work. When I returned after a holiday I was shocked to see so many thin grey faces and so many flabby babies.

The doctor orders glaxo, virol, or cod-liver oil, but few can afford to take it. There is no fuss made and no cadging; it depends entirely on the sharpness of my lookout whether they go off without their glaxo, &c., or whether I can catch them and make my price fit as nearly as possible to their needs. This last, of course, depends on the generosity of those who send special subscriptions for this purpose. My experience now is, as always, that the mothers rise to the occasion, making the very best of a very bad situation. I overheard one mother of a large family say, "Oh, yes, they gave me a beautiful tonic at the hospital, but I'm afraid to take it, it makes me so hungry."

I have this morning waited for 1½ hours in a queue for my coal permit. There were about 100 women there, most of them with babies, and it was bitterly cold. There were the usual fun and chaff, but I cannot help feeling that under it all the women's courage is nearly at breaking point. It has gone on so long; during the war they stuck to it, counting the weeks till peace came, and now it seems to have no end. A few are bitter, most are deadly patient. I say deadly, because that is what it really is.

I am, Sir, yours faithfully,

April 18th, 1921. TRAVELLER.

THE COLONIAL MEDICAL SERVICE AS A CAREER.

To the Editor of THE LANCET.

SIR,—In Sir James Kingston Fowler's address to the students of the Middlesex Hospital on the advantages of the Colonial Medical Service, published under this title in your issue of April 9th, in his remarks on the Kenya Colony, he referred aspirants for service in that colony who desired further information to three very admirable and charmingly written books by three eminent medical men recording their impressions. The scope of these three books, and the attitude of their writers, is very sufficiently indicated by their titles. Sir John Bland-Sutton's is one which could well be in the library of every East African medical officer for the accurate and interesting information with which it is packed. The other two are more evanescent in character. In a young colony which is struggling very hard to evolve itself, the changing conditions which take place from six months to six months are simply unbelievable except to those who have experienced them. It seems, therefore, somewhat of a pity that the official propagandist of the Colonial Office can do no better than refer to books published some 10–11 years ago. As to what we are now asked to believe, I quote the following from Sir Frederick Treves's book, p. 103:—"The country is healthy. There are no mosquitoes, and no malaria. There is no prevailing disease"—an amazing statement, which, at the time the book was published, occasioned no little comment in our small medical world. The hold certain endemic diseases had on the country was well known to us at the time; while the potentialities of others—which subsequent years' experience have proved—were always before us.

The Colonial Office and the local Administrations of the different colonies are yearly in receipt of annual medical reports, special reports, and investigations on every occurrence affecting the health of the community; of which nothing more is heard. Without claiming an unassailable accuracy for the facts and figures supplied, it seems to me that the time has now come when the Colonial Office might well consider the propriety of collating all these reports for the last five years by a competent editor, under the heading of each colony. If such a handbook was published every five years—the Germans did it for their East African possession—it would be invaluable as a permanent book of reference, as a record of the health progress of the colony; and, finally, it would go far towards determining the relative position to be assigned to each colony for climate and health.

I am, Sir, yours faithfully,

A. D. MILNE,

Late P.M.O., Kenya Colony.

Addison-road, Kensington, April 16th, 1921.

DELAYED REPORTS.

To the Editor of THE LANCET.

SIR,—THE LANCET has always taken such great pains to ensure accuracy in its editorial columns, and statements contained in them are therefore looked upon as absolutely reliable, that I must ask you to allow me to point out a very important exception. In the issue of April 16th, p. 819, you say that the medical officer of health for the county of Gloucester deplores the failure of subordinate health officers punctually to submit their sectional reports. A medical officer of health of a district is not a subordinate health officer and is not so described by the medical officer of health for Gloucestershire. He does not even make a report either to the county council or to the county medical officer of health. He reports to the district council which he serves and is required to send a copy of that report to the county council.

No one deplores the delay in issuing their reports more than the medical officers of health of districts. But what is the reason for the delay? In the case of whole-time officers it is the fact that, with one or two exceptions, the whole of the clerical work of his appointment has to be undertaken by the medical officer of health himself. Unlike the medical officer of health of a large town or of a county, he has not even an office provided for him, much less a staff of secretaries, clerks, and office-boys. He has to keep his own records and make his own returns. His correspondence must be written with his own hand, and he himself must keep a registry and file away documents. I have before me the annual report of one of these medical officers of health covering 120 printed pages foolscap and another 130 pages royal octavo, each with many tables. The mechanical labour of writing these pages for the printer, even by an expert clerk, would take many days. But it has to be done by the medical officer of health at odd moments which he can spare from his routine work. For years the medical officers of health concerned have been clamouring for the removal of this disability, and if the Ministry of Health, who also "deplore" the delay in the issue of the reports, and county medical officers of health instead of deploring would take the obvious steps to effect a remedy some good might accrue.

I do not like a *tu quoque* retort, but the temptation in this instance is too great to be resisted. Dr. Martin's report to the Gloucestershire Education Committee as school medical officer consists of 18 pages (including the title-page and index) and 12 tables, demy octavo. This report is dated May 28th, 1920, and I do not suppose Dr. Martin does much actual clerical work.

I am, Sir, yours faithfully,

Hereford, April 16th, 1921. HERBERT JONES.

⁂ The question, as so often, is one of terminology. Dr. Herbert Jones is right, but are we wrong? It is true that the district medical officer does not report direct to the county medical officer, but he has to forward to the county council a copy of the report made to his own authority. To this extent, surely, the county officer is suzerain to the district officer.—ED. L.

CONGENITAL SYPHILIS.

To the Editor of THE LANCET.

SIR,—The discussion recently held by the Royal Society of Medicine upon the subject of Congenital Syphilis has brought before us the marked differences of opinion with reference to the incidence of the disease and the need for further research and investigation, both in the laboratory and at the clinic. Many of us, and especially those who are engaged in children's work, have been much concerned to know the amount of mortality and morbidity due to congenital lues amongst the child population. While, on the other hand, there are those of us who believe that syphilis is a considerable cause of abortion, miscarriage, still-birth, and death within a few weeks of birth; and while we also recognise that syphilis manifests itself only too frequently during the early months and years of life, yet the evidence presented to us by the examination and care of large numbers of sick infants and children does not appear to support the suspicion that any considerable amount of mortality or ill-health is due to this cause. On the other hand, there are others actively engaged in the same kind of work—especially, I think, lady doctors—and equally imbued with the importance of arriving at the truth, who think differently, in that they are convinced that quite a considerable amount of mortality and morbidity throughout infancy and early childhood is due to congenital syphilis. One was therefore relieved to see from the Report of the Proceedings that the majority of the speakers did not support the views of those who believe that congenital syphilis is an important and frequent cause of mortality and morbidity during later infancy and childhood. While all of us realise the importance of free and open discussion, without at the same time committing ourselves at this stage to anything in the way of a definite opinion, yet many have viewed with concern the suggestions put forth in the medical journals that diseases and conditions, up to the present not considered to have a syphilitic basis, are after all due to the evil results of the disease. We are open to persuasion and proof. We meet with much persuasion, but the proof in the form of sound reliable scientific evidence appears to be small.

The Wassermann test in the hands of some workers appears to be sweeping into the net all kinds and conditions of disease. The results of the test in the hands of different pathologists are, however, so contradictory that one would challenge at once the advisability of allowing the test to stand as a deciding factor at the present state of our knowledge. All I think will agree that in the presence of active infection the test may be of the greatest value. During the secondary stage of adult syphilis its value is unquestionable, but in the early and late stages its value as a deciding factor is almost nil. As a test for congenital syphilis we have it on good authority that it may be negative in the early weeks, during the active manifestations of the disease it is positive in the large majority of cases, while in the later stages of the infection in childhood its value as a deciding factor again very considerably diminishes. Herein lies a difficulty. The fact that some of us believe that congenital syphilis is a comparatively infrequent disorder, but are at the same time willing to acknowledge that the test in the early and late stages is frequently negative places us in considerable difficulty when we endeavour to combat the suggestion that many disorders and defects considered in the past to have no relationship to syphilis are, after all, due to the disease, although not necessarily an active manifestation of it. We have from time to time been urged to seriously consider the proposition that mental deficiency, epilepsy, spastic paraplegia, pluriglandular insufficiency, nephritis, and, indeed, most of the disorders of infancy and childhood which possess an unknown ætiology may be due to syphilis. I have been asked to believe that "beading" of the ribs during the early months, bossing of the head, craniotabes, thickened skull, a posterior fontanelle which refuses to close by the sixth week, a fontanelle which closes too quickly, ridging of the sutures, enlargement of the liver, anæmia, hydrocephalus, congenital heart disease, and any conceivable thing that I am unable sufficiently to explain, are due to congenital syphilis. When I say that the blood is negative, that there are none of the usual manifestations of the disease present, and that the family history is clear, I am told that a negative Wassermann between the age of two weeks and two years is nothing to go upon, that the absence of the usual manifestations is quite common, and that the family history is rarely reliable because so much is forgotten or kept back by parents who are always out to fog the doctor. Naturally, I am a little nonplussed. I am asked whether I have tried a provocative dose of salvarsan, and when I answer that three gentlemen in America tried the intravenous injections of salvarsan upon non-syphilitic patients with a previously negative Wassermann reaction and obtained a positive reaction in more than 50 per cent. of the cases, the answer is received that surely if this is so I should try it on children and be convinced.

One decides to keep an open mind, and, taking mental deficiency as a test case, I try to find out its relationship to syphilis. I have a feeling that quite likely syphilis may have had something to do with it, and am impressed by the statements of Sir Frederick Mott as given before the Royal Commission on the Care and Control of the Feeble-minded (Vol. I., p. 453), but I also find that the Wassermann reaction used as a test by different workers in connexion with mental defect has given results which vary between 1·5 per cent. and 60 per cent. positives.[1] In the series showing the highest percentages cases are included where the parents or other members of the family have been found positive. The clinical examination of some 70 odd cases of mental deficiency under my care at the Meanwood Park Colony does not support the belief that many of these cases have suffered in the past with the disease. Except in two or three possible examples, the usual signs of lues tarda are not found. I note, however, that the family history of the patients provides many examples of mental instability in the parents.

Taking epilepsy in more detail, the blood test was performed on some 120 cases attending my epileptic clinic at the Leeds Public Dispensary, and 25 per cent. of the cases are returned as positive. Examination of the positives shows that several of the strongly positives are frankly syphilitic, with the general make-up of cerebral syphilis or congenital general paralysis. Some of the positives are described as "slightly positive," and experience with medical out-patients and at a venereal clinic has profoundly shaken my faith in the "slightly positive" result. Excluding the obviously syphilitic type of case amongst the epileptics, and excluding these very questionable "slightly positive" cases I am left with a positive percentage of 16. I find also that a 7·4 percentage was found amongst 418 adult epileptics.[2] I am then reminded of the fact that Dr. Paul Fildes reported to the Royal Commission[3] that approximately 8 per cent. of 1002 out-patients attending the London Hospital were found positive, no patient being included who came to the hospital for reasons connected with syphilis. To complete the picture I take careful note of the parents' and grandparents' reproductive histories. Excluding all those cases that have given positive results I find that in the immediate families 154 infants were lost out of 597, a proportion of 1 in 3·8. In considering the infant loss in the families of the grandparents I take the family on the paternal or maternal side that shows the greater infant loss, arguing that if the disease has been passed down it will most likely have been so from the side showing the greater death-rate. In this way it is found that 274 infants were lost out of 663, a proportion of 1 in 2·4. One was therefore hopeful that evidence had been found suggesting that epilepsy may possibly be a third generation manifestation. Before jumping to conclusions I decide to examine the family histories of controls—patients not suffering with epilepsy or syphilis from the clinical standpoint. Fifty-six controls show a loss of 73 infants amongst 336 brothers and sisters, a proportion of 1 in 4·6, and a consideration of the families of the grandparents and again taking the heavier mortality side, I find that 128 were lost out of 324, a proportion of 1 in 2·5.

---

[1] Mental Defective Children, Shuttleworth and Potts, p. 95.

[2] Final Report, Royal Commission, Venereal Disease, p. 17.

[3] Final Report, Appendix XII., p. 139.

Dissatisfied and unconvinced, I turn again to the infant, and especially to the infant suffering from convulsions, "consumption of the bowels," marasmus, hydrocephalus, or mental defect—the type of child that died in the family of the grandparents—and I examine it both from the point of view of the blood and for any history or manifestation of active syphilis, and my results, with few exceptions, are consistently negative. As one amongst others who is merely desirous of arriving at the truth, I welcome any expression of opinion or investigation which will help to elucidate the difficulty, but I am reminded of the fact that many years ago the profession began to make themselves believe that large numbers of children were suffering from scurvy, which had at that time begun to be talked about and investigated, and therefore I am alarmed lest we should allow ourselves to exaggerate unduly the importance of syphilis as a cause of the diseases and defects of present-day infants and children.

I would, therefore, earnestly put forward a plea that we should refuse to accept any figures or statistics that are not supported by weighty clinical and pathological evidence. If congenital syphilis is really more prevalent than most authorities have dreamt of in the past it is clearly of first importance that it should be proved so, and that we should act accordingly. If, however, we are taking a too pessimistic and exaggerated view of the situation let us carefully avoid the danger of misleading the public into the same exaggerated belief.

I am, Sir, yours faithfully,

Leeds, April 14th, 1921. C. WILFRED VINING, M.D.

THE FIGURES OF VENEREAL DISEASE.

To the Editor of THE LANCET.

SIR,—In THE LANCET of April 2nd I drew attention to a statement made by Lord Knutsford in the House of Lords that "at the London Hospital alone they had 23,000 new cases of V.D. last year." He added that the figures of V.D. in this country were almost too great to be believed, in which opinion I fully concurred; in fact, I should be inclined to omit the word "*almost*."

In your issue of last week Lord Knutsford corrects his original statement, says that he misread his brief, and that the increase of 23,000 was at the London hospitals, not at the London Hospital. Here, again, there appears to be some inaccuracy in Lord Knutsford's figures, for the total number of *new* cases in attendance at the V.D. clinics at the London hospitals was in 1919 28,265 and in 1920 31,046, which shows an increase of 2781 for last year. Of these new cases 5118 were diagnosed as not suffering from V.D. in 1919 and 6592 in 1920, so that if these cases are deducted the total increase last year amounted to 1307.

It is to be hoped that later some information will be given as to what the figure 23,000 was really meant to allude. My own impression is that owing to the "very energetic propaganda" *carried out by the N.C.C.V.D.* the incidence of these diseases is now declining, in confirmation of which opinion I may state that at the London Lock Hospital there has been a falling off in the first quarter of this year of 569 new patients and 994 attendances in comparison with the corresponding quarter in 1920.—I am, Sir, yours faithfully,

J. ERNEST LANE.

Queen Anne-street, W., April 18th, 1921.

To the Editor of THE LANCET.

SIR,—In the *Daily Telegraph* of March 17th last Lord Knutsford is reported as having said, in a speech which he had made on the previous day in the House of Lords, that there were at the London Hospital 23,000 new cases of venereal disease last year. In THE LANCET of April 16th Lord Knutsford admits that he has made a mistake, and that the figure of 23,000 refers to the London hospitals and not to the single institution of the London Hospital.

The figure of 23,000 having been corrected, may I venture to draw your attention to the term "new cases"? All those who have any dealings with hospital "new cases" know that such a description may bring into account cases of the following nature:—

1. Cases which, having attended the previous year, are *still under treatment* the following year—i.e., cases which, having attended (*e.g.*, in 1919), are still being *treated in* 1920.

2. Cases which, having previously attended one institution, now attend at another, and are possibly drifting on to yet another.

Further, in my experience, cases are sent up to the various clinics concerned in the treatment of venereal disease, which are not venereal. I venture to state that if the term "new cases" includes cases coming under the above descriptions the figures of incidence of venereal disease may be reduced below even the 23,000 at the London hospitals.

I am, Sir, yours faithfully,

RALPH THOMPSON.

Queen Anne-street, W., April 18th, 1921.

HERPES OR CHICKEN-POX?

To the Editor of THE LANCET.

SIR,—As the relationship between herpes zoster and chicken-pox is at present attracting some attention the following case may be of interest.

E. L., male, aged 31 years, complained of pain in the left buttock and extending down to the knee. It was dull and constant in character, and was becoming worse since its onset two days previously. There were no physical signs, and the patient was given salicylate of soda. Two days later he noticed a rash on the buttock. The pain in the leg was less, but it still felt sore. However, the patient felt ill and giddy, and was sweating. He also noticed a few spots in his mouth and on his chest. The next day there were more spots on his chest and some on his face.

When he was seen again, the rash extending in a scimitar-like form over the middle third of the buttock proved to be herpes zoster, while the generalised rash was chicken-pox.—I am, Sir, yours faithfully,

W. G. VERNIQUET, B.Ch., M.R.C.S.

Kingsbridge, Devon, April 13th, 1921.

THE ÆTIOLOGY OF SUBPHRENIC ABSCESS.

To the Editor of THE LANCET.

SIR,—In his clinical lecture on Subphrenic Abscess, published in THE LANCET of March 19th, Mr. C. H. Fagge speaks of the limitation of the disease being due to "a former localising peritonitis." This statement may be frequently true, but when engaged in pathological work the formation of a subphrenic abscess used to appear to me to be a remarkable illustration of the wonderful power of the great omentum to form adhesions, while the peritoneum covering the viscera may not be able to react to irritation in any other way than to produce pus.

In the case of a perforating gastric ulcer on the anterior surface of the stomach near the lesser curvature, if the escape of the contents should not be too rapid, inflammation spreads slowly over the surface of the stomach until the great omentum attached to the lower border of the viscus is reached. Adhesions are there formed between the omentum and the abdominal wall, arresting the downward spread of the inflammation. The spread to the right is prevented by adhesion of the omentum to the lower border of the falciform ligament, while adhesions in the neighbourhood of the spleen prevent leakage in that direction. A closed cavity is rapidly formed, bounded by the portions of the abdominal wall and diaphragm in front and above, with the left lobe of the liver and the anterior surface of the stomach below. The peritoneum covering these surfaces, instead of forming adhesions, secretes pus, and the abscess is formed.

In the case of a subphrenic abscess following appendicitis again it is the great omentum which limits the disease. The inflammation travels upwards on the outer side of the ascending colon, and its course is watched and directed by the great omentum, which gives rise to adhesions between the ascending colon and the abdominal wall. Eventually the inflammation reaches the liver. It may there form an abscess below the liver, limited in its spread to the right by adhesions of the great omentum to the lower border of the falciform ligament, but although pus may first collect below the liver, the inflammation generally spreads above also, and a subphrenic abscess to the right of the falciform ligament makes its appearance.

I am, Sir, yours faithfully,

Norwich, April 14th, 1921. THEODORE FISHER.

LIGHT AS A REMEDIAL AGENT.

To the Editor of THE LANCET.

SIR,—Your remarks, under this title, associated with my name, in the issue of March 19th, p. 603, have caused me considerable pain and annoyance. They have been copied in many daily and weekly newspapers, and unfair and foolish comments have been made. I have received many letters upon the subject, mostly abusive. I am not astonished at the lay press taking the matter up, for you have done your best to make me appear ridiculous.

Your opening remark is incomprehensible, what you mean by "gracious to say it" I fail to understand. You then say that I had the courage to denounce sunlight as a "harmful agent in the human economy." Your source of information is a typescript which I sent to you last October, which you had in your possession when you accused me of denouncing sunlight. My denunciation reads as follows:—

> "Sunlight is the most powerful agent under which we survive. If it were completely withdrawn vitality would cease; its varying quantity reaching the earth has an exact relation to the earth's vitality. In parts of the earth whose sunshine is *regular and abundant great fertility*, human and vegetable, prevails, and where it is less regular and less abundant relative sterility prevails. Where it is seasonal, as in the temperate climes, fertility is coincident with its greatest amount. The gradual increase in the amount of sunlight in the springtime is coincident with rutting in animals and germination of the seeds in the earth. Delay in its reception retards both conditions, and early reception forwards both.
>
> Animals and plants are conscious of its over-exhibition, and only those which possess some protective power are able to survive. Animals which by their volition remove their bodies from its excessive influence, or which possess some protective skin *reflex acting automatically*, are able to use its power to their advantage, whilst stationary life defective in power of changing its transparency withers and dies."

I contend that this is common knowledge and that to make such a statement requires no courage, nor is it a denunciation. Had I quoted the classical example of the survivors of the Sicilian expedition as you suggest I should have displayed my ignorance of anatomy and of the physics of the higher frequencies of the solar radiations. You say:—

> "Dr. Holt regards sunshine as a cause not only of sunstroke, but of anæmia, chorea, and poliomyelitis, and standing in special relation to such epidemic diseases as typhoid, measles, and scarlatina."

The term sunshine as applied to my argument is a lax one, and is not once used by me in the argument. It occurs when I say "whose sunshine is regular and abundant." With regard to sunstroke, anæmia, and typhoid, there is no evidence in the typescript supplied to you that I regard sunshine as their cause. Sunstroke and typhoid appear (along with 20 other names) on a printed paper supplied to each of the attending members as "Conditions suggested as having an intimate relation to excesses of sunlight." Anæmia does not appear in the list.

The remark which appears in the typescript concerning chorea is as follows:—

> "Chorea is a disease occurring frequently in young children, especially in the spring (Osler says that relapses occur in the spring, and I think the same is mentioned in most text-books), at the time when the chemical frequencies re abundant."

Referring to poliomyelitis I say:—

> "I hope you will see that the view running through this paper is that nervous disorders *may* be due to electrical action of the solar radiation upon the electrons of the central nervous system conveyed through the terminal nerves and it is in *this way that I* suggest poliomyelitis arises."

My regarding measles and scarlatina as having a special relation to sunshine is based upon the following:—

> "Measles and scarlatina present a curious problem. They are largely summer diseases, known to be infectious, yet *in both these illnesses* the whole of the skin, including the face and hands, becomes suddenly opaque to the chemical frequencies of light. This is worthy of study."

You misquote me, "admitted during the daytime," I referred to *severe* accident cases *conveyed in an open ambulance*. Your reference to the tuberculosis cases is neither fair nor exact. I say that—

> "Our cases demand a *scientific hygiene adapted to* each individual. ...... Patients have lost superficial fat, the skin has become thinner, the blood anæmic, and the condition is one highly susceptible to the chemical energies of the sun. Therefore the sun must be applied to them with the highest degree of refinement; they react to it quickly; a proper dose is beneficial, an overdose fatal. ...... The Daylight Saving Act when it *first* came into operation caused nearly all my dispensary patients to lose from one-thirtieth to one-fortieth of their body weight during the first three weeks. Many recovered after the first month, but it was fatal to a few."

Your sense of humour is *peculiar when you find* delightfulness in my manner in making the following observations:—

> "The proof that a fair skin transmits the visible frequencies is shown in the transillumination of the face and the comparative transparency of the hands on bright summer days. Dirty hands are not so transparent as clean hands. This may be the explanation why young children dislike being washed. Mothers say that their children are never so happy as when they are dirty. Direct sunlight does give pain to certain skins, and even indirect sunlight gives considerable pain to the dermis when denuded of its epidermis. My own experience in dressing extensive burns taught me this fact very early, compelling me to postpone dressings until evening and then only by candlelight."

"The malignant rays of the sunlight" does not appear in the typescript. The expression is one I do not precisely understand; I suspect it is intended to be sarcastic. If it is sarcastic it shows a lack of sympathy with young children.

The principal *object of my paper is to call attention* to the possible misuse of sunlight for young children and for patients who are more or less at our mercy, and had I not seen such misuse, entailing considerable suffering, I *should not have taken* the trouble to compile a paper on the subject. It is a common experience to see babies exposed to a brilliant sun whilst the attendant, who has an older and better developed skin, shades herself with a broad-brimmed hat or a parasol. Patients frequently cover their heads with the bedclothes and some hide themselves under the beds to escape the sunlight. Surely an appeal to save such suffering is unworthy of ridicule.

In your criticisms you fail to note what I consider to be my strong points—viz., the occurrence of epidemic diarrhœa and nervous disorders in young *children at* the time when their pigmentary protection is most deficient, and their powers of seeking the shade are non-existent. Finally, I may remark that it is inconsistent with ordinary intelligence *to consider that* the most powerful agency under which we survive is harmless under all conditions, and equally beneficial to everyone irrespective of integumentary power of *reception or protection*.

I am, Sir, yours faithfully,

R. CRAWSHAW HOLT, M.D. Durh., M.R.C.P. Lond.

Didsbury, Lancs., April 11th, 1921.

*** We are happy that our readers should learn Dr. Holt's views in his own words. If we do not wholly agree with those views we may none the less express regret at the personal annoyance which the criticisms have brought on him.—ED. L.

Obituary.

HENRY BARNES. O.B.E., LL.D. McGILL, M.D., F.R.S. EDIN.

Dr. Henry Barnes, whose death at Carlisle on April 12th we briefly recorded last week, held a long record of distinguished service for his profession and in public life. Born in 1842 near Wigton in Cumberland, graduating with honours at Edinburgh University in 1864, he settled in Carlisle in 1866, holding his first public appointment as physician to the Carlisle Dispensary. In 1873 he was appointed honorary physician to the Cumberland Infirmary, where he became chairman of committee and finally a president, devoting to this institution the energies of a long life. His organising ability was freely expended in collecting funds for the extension and improvement of the building, in which his professional and social gifts, freely bestowed, made him beloved and respected. During the war Dr. Barnes acted as honorary secretary and treasurer to the Cumberland Branch of the British Red Cross Society, showing himself a discerning administrator. His public spirit found scope in his work as county magistrate from 1889 on, becoming chairman of the Cumberland Ward Justices from 1904. He was no mean antiquarian and archæologist; his contributions to scientific literature comprised papers on Roman Medicine and Practitioners, Roman Medical Inscriptions in Britain, and Hadrian's Wall. As President of the British Medical Association in 1896 he gave a notable address on the Medical History of Carlisle. His retirement from practice did not curtail his efforts for the public good, and he will long be remembered in Carlisle as one who served his fellows. Dr. Barnes married in 1873 Emily Mary, daughter of Thomas Barnes of Bolton, and is survived by his widow, a son, and a daughter.

PETER THOMAS DUNCAN, M.D., B.S. LOND.

Dr. Duncan, of Croydon, whose sudden death on Wednesday, April 6th, was recorded in the last number of THE LANCET, was one of the best all-round practitioners of his day. As a student at University College Hospital he distinguished himself highly among strong competitors; the London University honours lists of that time reveal a contest of stalwarts, and Duncan's name occurs again and again among them. In 1874 he graduated M.B. with honours, and on the same occasion took the gold medal at the B.S. examination. He qualified again for the gold medal when taking his M.D. two years later. He was appointed physician's assistant at University College Hospital, and later was elected to a Fellowship of the College. After a short period of general practice elsewhere, Duncan joined Dr. H. J. Whitling at Croydon in a partnership, of which he afterwards became the head, and he was chiefly responsible for an organisation among a group of practitioners which allowed free scope to their several specialist experience. Duncan himself became physician to the Croydon General Hospital. He was secretary of the East Surrey District of the British Medical Association from 1885 to 1893, and in 1897 was President of its South-Eastern branch. In and around Croydon he held the regard and confidence alike of his fellow practitioners and of the public. His diagnosis, especially in cases of cardiac, circulatory, or pulmonary disease was very sound, and in the difficult problems of prognosis he was surprisingly accurate.

An intimate friend and colleague writes thus of Dr. Duncan: "Much of his success as a leader of a group of men was due to his practical business qualities, knowledge of human nature, and shrewd foresight. It might have been said of him: 'He read much. He was a great observer, and he looked quite through the deeds of men.' Had Duncan chosen the law for his profession he might have made a first-class judge, for he had a singularly judicial unbiased mind. He obtained loyalty from his colleagues of an unvarying kind, due to his personal charm securely based on sincerity, freedom from affectation, and from professional jealousy. The degree of conscientious care that he bestowed upon his patient was a reflex of a high standard in work cherished to the end of life."

Dr. Duncan leaves a widow, a son, and three daughters to mourn their sudden loss, and a very large circle of patients and friends will miss him sorely. His brother, Dr. William Duncan, gynæcologist to the Middlesex Hospital, predeceased him.

PETER TYTLER, M.D. ABERD.

Dr. Peter Tytler, whose death occurred, at the age of 72, on April 9th at his residence in Withington, was for over 40 years a familiar figure more especially in the Ancoats district of Manchester. Brought up at Tyd-Mar in Aberdeenshire, he was the last male member of a family that had lived there for three centuries. Proceeding to the University of Aberdeen, he took the degrees of M.B. and C.M. in 1872 with highest honours and the M.D. in 1875. After graduating he acted as resident medical assistant at the Royal Asylum, Aberdeen. He came to Manchester in 1876, and by energy and assiduous attention to his patients acquired a substantial practice. After a time he was appointed an honorary surgeon at Ancoats Hospital, a position which he held until ill-health compelled him to resign in 1916, when he elected to reside in Withington. A tall and striking personality, his figure was well known, and his many good and unobtrusive deeds were highly appreciated by the community in which he spent his active existence. In spite of the physical impairment of his health which led to his retirement, Dr. Tytler retained his bright and cheery disposition and remained mentally very active.

FREDERICK J. BURMAN, M.R.C.S., L.R.C.P. EDIN.

THE tragic death of Dr. F. J. Burman removes a very well-known figure from the South Yorkshire district. Whilst cycling to visit a patient on Friday afternoon he was accidentally knocked down by a motor-car and died from the effects a few hours later. Born at Wath-on-Dearne, he succeeded to the practice which his father and grandfather had held before him. He had seen his native place change from a quiet, picturesque country town to a busy industrial centre at the heart of the South Yorks coal-fields, and his interests had extended to everything which could promote its welfare. In addition to a large general practice, in partnership with Dr. T. Crowley, he was medical officer of health for the district, and had charge of the Fever Hospital. He was also an active member of the staff of the Mexborough Montague Hospital, where, indeed, he passed away after his accident. He was particularly interested in ambulance work and was known over a wide area as an authority on the subject. His help as a judge in prize competitions was largely sought, and he had arranged to occupy this position in the annual competitions amongst the South Yorkshire Colliery teams which were held the day after his untimely death. Kind-hearted, unselfish, and modest, he was a practitioner of the best type, and his loss will be deeply felt over a wide area.

ALFRED ERNEST WILLIAM RAMSBOTTOM, F.R.C.S.I., M.D. DURH.

THE Hon. A. E. W. Ramsbottom, late Administrator of the Orange Free State, died in London, where he was doing special post-graduate work, on April 16th, as the result of heart failure after a severe operation. Born at Grahamstown in 1860, he was educated first at Bloemfontein and then at Dublin where, after a brilliant career as a medical student, he qualified in 1882, becoming F.R.C.S.I. in 1896. He obtained the M.D. Durh. in 1902. On returning to South Africa he practised first at Fauresmith and afterwards at Bloemfontein. During the South African war Dr. Ramsbottom was appointed chief medical officer to the Free State Forces, and in 1907 accepted the Treasurer's portfolio in the Cabinet of the Orange River Colony. On the formation of the Union he was appointed First Administrator of the Orange Free State, a post which he held till 1915, when he returned to private practice at Heilbron. For a time he presided over the South African Medical Association.

Parliamentary Intelligence.

HOUSE OF COMMONS.

Wednesday, April 13th.

Public Health (Tuberculosis) Bill.

On the motion for the second reading of the Public Health (Tuberculosis) Bill,

Sir A. Mond (Minister of Health) explained that the measure was introduced to provide for commitments resulting from the passing of the National Health Insurance Act, 1920. The effect of the Bill was to take away from the Insurance Committees the responsibility of providing institutional treatment for tuberculosis in the case of insured persons as from April 30th, 1921, the date when the sanatorium benefit ceased. The Bill was therefore extremely urgent if the machinery by which people had enjoyed sanatorium benefit was not to come to a standstill. It was provided by the Bill that the county and county borough councils should take on the work of dealing with tuberculous persons both insured and non-insured. Of the 145 county and county borough councils in England and Wales, 124 had already made such arrangements, and the Bill imposed no fresh obligations on those councils. Of the remaining 21 councils, all but one had made some provision for the treatment of tuberculosis, but in two or three cases the provision only extended to dispensaries, and in others the arrangements of the councils for treatment in sanatoriums or hospitals did not make full provision for insured persons. The great bulk of the county and county borough councils had agreed with the Ministry of Health to make full arrangements, and so far as they were concerned the Bill was really an agreed Bill. He understood that the councils that had not yet fallen into line were practically ready to do so if they understood that the obligations were statutory ones; but in the event of any local authorities failing to carry out their duties under the Bill, power was given to the Minister to make the necessary arrangements and charge the authority with the cost. He wished to make it clear that he had no objection if it was thought desirable to insert an amendment in Committee making it quite certain that the arrangement that had been made by the Welsh National Memorial Association with the various county councils and local authorities in Wales would be safeguarded.

Mr. Ormsby-Gore welcomed the Bill, which, although it was not much more than a skeleton, proceeded in his view on the right lines. Everything in a matter of this kind depended on the whole-hearted coöperation of the local authorities, without which all efforts to improve public health in this country were doomed to failure. The campaign against tuberculosis required strategy as well as tactics, and a complete strategetic policy was the most urgent necessity at the present moment. One of the lacunæ was this: tuberculosis was notifiable since 1912, *but it was notifiable to the district medical officer*, who passed on his information confidentially to the county medical officer. This seemed to be a mistake, and if they were going to follow through the life-history and the treatment of the disease they must get over that administrative difficulty. After-care *needed far more attention than it* received at present. Also they had to consider the children, the food, and general hygienic conditions of the country.

Mr. R. Richardson welcomed the Bill on behalf of the Labour Party, but considered that matters should not be left so much to the local authorities in what was a national question, to be dealt with at the expense of the State. He recognised the difficulty of diagnosing the disease in its early stages, but he hoped the medical profession would make such an advance that that difficulty would be overcome. The greatest omission in the Bill was the question of after-treatment. Provision should be made for adequate nursing, pure food, pure milk, and everything that was necessary for the care of patients. It ought to be an instruction to every local authority that it should have an after-care committee. Every local authority ought to provide an open-air school for children suffering from the disease.

Dr. Nathan Raw pointed out the loss to the country in man power and money from a preventable disease. If, he said, Clause 3 were made mandatory rather than permissive in respect to the coöption of members of Insurance Committees, they would get the benefit of the services of those who were specially trained. A well-equipped sanatorium was the best method of treating the great mass of the people, but unless all the expense and trouble were to be wasted, local authorities should have the power to appoint an after-care committee, which should be a statutory one, to look after the patient and see that he was enabled to carry on in some degree the treatment he had received in the sanatorium. Something must be done to enable the worker who had been crippled with tuberculosis to earn a living, and the isolation of advanced cases must be seriously taken in hand.

A National Disease: Systematic Organisation Required.

Captain Elliot said that in Scotland tuberculosis was killing about 800 people a week. It was estimated that in the United States of America in the year 1903 tuberculosis cost the country £66,000,000. That was only the direct cost; as to the indirect cost, it was utterly impossible to get any sort of estimate. They were all agreed that the disease was one which they must treat; it was a national disease and ought to be treated by some systematic scheme of organisation. The principle of dividing the country into areas and making one authority in each area responsible for dealing with the disease had proved effective in dealing with other forms of disease, and they had every reason to hope that it would be equally effective in dealing with tuberculosis. They had the consolation of knowing that the work so far carried out had been effective. The number of deaths in 1914 was 50,000. In 1915 housing conditions were not noticeably worse, food was better, and employment was good, while prices had not reached the terrifically high point to which they soared later. But the deaths in that year increased by 4000. In 1916 they remained at the same total of 54,000; in 1917 they reached 55,000, and in 1918, the influenza year, they went up to 58,000. In 1919 they fell to 46,000, and in 1920 there was a further fall to 42,000. A certain amount of that decrease was undoubtedly due to the remedial measures introduced by the then Minister of Health, but a large amount of it was due to good trade in the country, and he was sure that every medical man would join with him in warning the House against the almost inevitable disturbance in our vital statistics which the present industrial crises would bring in their path. Housing was not noticeably better in 1920 than in 1918. Our vital statistics were very much better than those of any other country in Europe just now, and better almost than those of any other country in the world. He had been able to get some figures for other countries. In 1919 our death-rate was 125·8, and in 1920 it was 112·8. In Prague, where the conditions were fairly comparable with those in this country, the death-rate was 386, as compared with our 112·8. In Warsaw it was 591; in Vienna, 490; and in Cracow, 616. These were the figures for the disturbed areas to bring home what we might fear if similar disturbed conditions began to prevail in this country. A very terrible state of things might easily arise, for we had no special immunity against disease in this country. He thought the scheme of the Ministry of Health was the best way of dealing with this matter. They had got child mortality down from 110 to 80 to-day. It was said that was simply to do with the care of mothers and had nothing to do with clinics. He had discussed the matter with a medical officer of health for a borough not far from London, where the death-rate of children attending the clinic was 40, whereas the death-rate of children not attending the clinic was 77. This showed, at any rate, that the careful mother found the clinic an advantage, and the same general principles applied to tuberculosis would be of the greatest benefit in bringing down the death-rate from that disease. We had a splendid chance just now. Influenza had swept out a large number of people who would probably have become acute cases of tuberculosis. We had now a much better chance than we had ever had before of reducing the disease to practically negligible proportions in this country. Sailors, of all people, were most liable to phthisis owing to the small amount of air space they had in ships—about 45 feet. as compared with about 400 cubic feet for the tramp in the common lodging-house—and this would have to be treated as an international problem. With regard to the general treatment of after-care, the experience of the *Ministry of Labour would be of the* utmost value to them in the long run. They needed a sort of disabled man's roll, some sort of national scheme for a certain proportion of places in industries being reserved for the casualties of industry. He invited the coöperation of the Labour Party in some scheme of that sort. *He also begged them not to* adopt, as they had sometimes done in the past, a stand-offish attitude towards the voluntary dispensary system, and particularly in London. He suggested that there should be some sort of clearing-house system before men were definitely marked off for sanatorium treatment. Full advantage of modern methods of diagnosis should be taken. The clearing-house system would enable the whole medical science to be concentrated on a particular case, and then it could be determined definitely, after some residence in hospital—perhaps three or six weeks—whether a person needed to start the treatment. It seemed incredible that the Royal Hospital for Diseases of the Chest, with 100 years of history behind it, was at this moment in danger of being pulled down, and had come to an arrangement by which an equal number of beds would be erected in conjunction with a large general voluntary hospital. He would ask the London members if it was not possible for them to enter into some arrangement by which the organisation of this hospital could not be made available for clearing-house work under the new London County Council schemes which would be necessary, or which they had already set up with the approval of the Ministry of Health. The great Sanitary Acts of this country had brought down the death-rate to 13·5, far below the death-rate of other countries. Work done on the fabric of the State, the people, was work done on the foundation-stone of the building of Empire, and was in the long run far more important to the Empire than any amount of flags which might be hoisted, although they might appear a great deal more imposing at the time.

Major Molson thought the importance of this Bill far outweighed any question of economy at the present time, but he would not like the enthusiasts to persuade them to go in for too great expense and then arouse opposition. As a medical man he wished to say that early treatment of tuberculosis was essentially the important thing. Plenty of accommodation was important, but there was no need for very elaborate buildings, where only a few patients could be taken in and where there would be a long waiting list. The medical profession felt rather bitter that the pledges given when the National Insurance Act was passed had not been fulfilled. He urged the Minister not to bring in many conditions or regulations, but to work with the local authorities and to get their free-hearted and hearty coöperation.

Mr. Johnstone, speaking as a member of the local authority which had been treating tuberculosis, agreed with the general approval that had been given to the Bill, but regretted that it had been considered necessary to remove the sanatorium benefit from the Insurance Committees. The one hopeful feature in the treatment of tuberculosis to-day was the work colony, the pioneers of which in this country were Dr. Marcus Paterson, of the Brompton Hospital, Frimley, and Dr. Varrier-Jones, of the Papworth Tuberculosis Colony, Cambridge.

Major Farquharson said, as he read the Bill, something like £400,000 would be available. Sanatorium treatment at present was nothing more or less than an experiment. Almost everything about medicine was experimental. The spending of large sums on institutional treatment was not either wise or justified by the results of the past. It was only one of the whole gamut of methods of treatment—one little stage which often came in, unfortunately, when treatment of any kind was more or less useless. One fault he had to find with institutional treatment was that it produced a certain degree of what he might call passivity on the part of the patient himself. The After-Care Association encouraged that passivity when often all that was wanted was to rouse the patient to the knowledge that he was his own keeper, that his health was in his own care, that by simple attention to hygienic rules he could not only give himself a higher, better, and stronger life, but he could cease to be a burden on his fellow men.

Mr. Myers welcomed the Bill, but expressed regret that it made no provision for preventive operations and no adequate provision for after-care treatment. He attributed the ineffectiveness of insurance committees to the appropriation by the medical profession of 6*d*. out of the 1*s*. 3*d*. that was available for all domiciliary treatment.

Sir A. Mond, replying to the points raised in the debate, said where doctors disagreed it was difficult for laymen to be dogmatic. They had been told that sanatorium treatment was a failure and also that it was most valuable; to an unprejudiced mind both statements were true. It had not achieved everything that was expected, yet he did not think anyone would say that it had not achieved beneficent results.

The Bill was read a second time.

Revised Scale of Fees for Admiralty Surgeons.

Captain Elliot asked the Secretary to the Admiralty whether he was now able to give an answer as to the revised scale of fees for Admiralty surgeons.—Mr. Amery replied: The revised scales of fees have now been promulgated in a Fleet Order, with the exception of those for medical examinations, which are still under discussion. I am sending the honourable and gallant Member a copy of the Order in question.

Hong-Kong Naval Hospital.

Commander Bellairs asked the Secretary to the Admiralty what was the maximum number of patients that could be accommodated at the Hong-Kong Royal Naval Hospital; what were the maximum and minimum numbers accommodated in 1920; and how many convalescents were sent from there to the Yokohama Royal Naval Hospital in 1920.—Mr. Amery replied: The maximum number of patients that can be accommodated in the Royal Naval Hospital, Hong-Kong, is 134. The maximum and minimum numbers accommodated in 1920 were 99 and 52 respectively. Eleven convalescents were sent from Hong-Kong Naval Hospital to Yokohama Naval Hospital in 1920. The latter was not reopened until June 16th, 1920, which is after the usual time of year for transferring convalescents thither from Hong-Kong.

Encephalitis Lethargica.

Mr. Gilbert asked the Minister of Health the number of cases of this disease which had been reported to his department in this country during the past 12 months; how many cases had proved fatal; and would he state what special steps his department had taken to deal with this epidemic.—Sir A. Mond replied: 1572 cases of encephalitis lethargica, to which disease my honourable friend no doubt refers, have been reported in England and Wales between April 1st, 1920, and March 31st, 1921. The deaths from this disease during the same period, so far as is known at present, amount to 495. The disease was made compulsorily notifiable on Jan. 1st, 1919, and since then special reports have been received from medical officers of health in practically all the cases which have been notified, while special inquiries have been made and advice has been given by medical officers of the Ministry in suitable cases. Simultaneously the pathology of the disease is being studied in association with the Medical Research Council.—Mr. Sexton: May I ask if the Minister of Health's department is itself quite free from this disease? (Laughter.)

Islington Medical Officer's Superannuation.

Lieutenant-Colonel Fremantle asked the Minister of Health if he was aware that the Islington Borough Council proposed to superannuate their medical officer of health after 39 years' efficient and energetic service (10 years under the Corporation of Sunderland and 29 years at Islington) at a rate which was not fixed on any definite scale, and was far below that usually granted to executive officers; and seeing that the Superannuation (Metropolis) Act, 1866, provided for the payment of superannuation at the rate of one-sixtieth of salary for every year of service, that the Act is intended to apply without discrimination between the employees of local authorities, that the Islington Borough Council have adopted this Act in superannuating their roadmen, scavengers, and other labourers, and that the medical officer of health has requested the protection of the Minister of Health against the non-application of the scale in his case, would he say what steps he proposed to take in the matter.—Sir A. Mond replied: I am making inquires as to this case, and will inform my honourable and gallant friend of the result.

Dental Legislation.

Mr. Raffan asked the Minister of Health whether it was still the intention of the Government to introduce a measure, during the present session of Parliament, for the purpose of carrying out the recommendations of the departmental committee on the Dentists Act, 1878.—Sir A. Mond replied: I am afraid that owing to the congestion of the Government legislative programme, legislation on this subject will not be practicable during the present session.—Mr. Raffan: Is my right honourable friend aware that his predecessor promised that legislation should be introduced if there was any general agreement on the subject; and if we are able to assure the right honourable gentleman that there is a general agreement and that little time will be occupied, will he reconsider the matter?—Sir A. Mond: I had no intention to introduce a Bill this session, and of course the programme of legislation is very much upset already, and I am also informed that there is very little chance of there being any agreement. Of course I shall be glad to look into the matter again, but I do not know how any Member or group of Members can assure me that there is going to be agreement, and I am sure the House does not want an autumn session.—Mr. Raffan: Will the right honourable gentleman be prepared to receive representations on the matter from Members of Parliament?—Sir A. Mond: I shall be very pleased.

THURSDAY, APRIL 14TH.

Public Health (Tuberculosis) Expenses.

The House went into Committee of Supply on the money resolution of the Public Health (Tuberculosis) Bill, Sir E. Cornwall in the chair.—The resolution was agreed to.

Ministry of Health Draft Order.

On the motion "That the Ministry of Health (Factories and Workshops, Transfer of Powers) Draft Order, presented the 28th February, 1921, be approved," Lieutenant-Colonel Fremantle said the Draft Order went to the root of the formation of the Ministry of Health. The formation of that Ministry was heralded with great words as regarded the prospects of the custody of the health of the nation, and to it were referred certain powers, while certain other powers were reserved that might be added afterwards. Thirdly, there was a general power of taking over other powers that might conduce to the national health. It was a very serious and sound criticism of the Ministry of Health in its original constitution and conception that the whole question of health in the factories, as administered by the Home Office, should have been excluded from the functions of the Ministry. However, they had some very small contribution in the right direction in this Order, which transferred to the Ministry of Health certain powers and duties of certain sections of the Factories and Workshops Act, 1901—namely, Section 61 (Employment of Women After Childbirth), Sections 97 to 100 (Provisions Relating to Bakehouses), Section 109 (Making of Wearing Apparel where there is Scarlet Fever or Small-pox), and Section 110 (Prohibition of Home Work where there is Infectious Disease). He hoped this might be the prelude to the natural transference to the Ministry of Health of the whole general conception and survey of health matters in factories and workshops.—The motion was agreed to.

Public Health Officers (No. 2) Bill.

This Bill was read a second time.

Medical Equipment of the Auxiliary Division.

Lieutenant-Colonel WALTER GUINNESS asked the Chief Secretary to the Lord Lieutenant of Ireland if he could say whether the Auxiliary Division had the same quota of the Royal Army Medical Service attached to them as would be provided in the case of a corresponding number of troops employed in active military operations; and whether they had special ambulance cars allotted to them for the conveyance of wounded men.—Mr. HENRY (Attorney General for Ireland) replied: The Auxiliary Division is not provided with its own special medical transports. Ambulances and other necessaries of medical equipment are borrowed from the regular forces as and when required, and this arrangement has been found to answer satisfactorily.—Lieutenant-Colonel GUINNESS: Has the attention of the right honourable gentleman been drawn to the terrible sufferings of many of the auxiliaries who have been wounded in the Longford Camp; will he make further inquiries and consult the Director of the Royal Army Medical Service in Ireland as to what steps have been taken to prevent a recurrence of these terrible occurrences to men suffering from grievous wounds who have been left lying in the open without proper attention?—Mr. HENRY: I will certainly bring this matter to the attention of the authorities.—Earl WINTERTON: In the case of the Longford Camp, there is a gross scandal in connexion with the wounded servants of the Crown who have been left lying about for 24 hours open to being mutilated by Sinn Feiners because no proper provision was made for them and because it was not the duty of the Army authorities to convey them to the hospital.—Mr. HENRY: The matter is receiving the attention of the authorities.

Medical Benefit Statistics.

Sir CROYDON MARKS asked the Minister of Health the total number of persons receiving medical benefit; the amount paid to them the first week in March, 1921, and the corresponding week in 1920; and the total number of persons in sanatoriums or institutions for the treatment of tuberculosis for the first week in March, 1921, and the corresponding week in 1920.—Sir A. MOND replied: The number of persons in England and Wales entitled to medical benefit is approximately 12,750,000. I regret that no figures are available of the number of insured persons actually receiving (*a*) medical treatment, and (*b*) cash benefits in particular weeks. The total number of insured persons in England and Wales who were receiving treatment for tuberculosis in sanatoriums or other institutions was 8922 on March 1st, 1921, and 8754 on March 1st, 1920. The actual number of non-insured persons receiving such treatment on those dates is not available, but the total number of beds available for non-insured and insured persons in approved institutions for the treatment of tuberculosis was 17,894 on March 1st, 1921, and 16,432 on March 1st, 1920.

Pay of the R.A.M.C. Officers in India.

Lieutenant-Colonel WALTER GUINNESS asked the Secretary for India whether the increases of pay of certain specified services serving in India promised in Indian Army Order No. 558, of October, 1919, and sanctioned to date from July 1st, 1919, had in the case of the Royal Army Medical Corps, taken effect only from Jan. 1st, 1920, instead of from the earlier date as in the case of all other corps; and what was the reason for this distinction between officers who were serving under identical conditions.—Mr. MONTAGU replied: The pay of Royal Army Medical Corps officers in India was increased in March, 1920, with effect from July 1st, 1919. Consequent upon an increase of pay granted to Indian Medical Service officers, with effect from Jan. 1st, 1920, a further increase has recently been granted to Royal Army Medical Corps officers, with effect from the same date.

MONDAY, APRIL 18TH.

Summer Time and Children's Health.

Mr. ROBERT YOUNG asked the President of the Board of Education whether any consideration had been given to the effect on the health of young children as the result of the operation of the Daylight Saving Act; whether the earlier hours of attendance at school and the consequently prolonged day reducing their hours of sleep had had any injurious effect; and, if so, what steps he proposed to take in the matter.—Mr. FISHER replied: I cannot add anything to the summary contained in Paragraphs 32 to 36 of the Report of the Summer Time Committee, 1917 [Cd. 8487]. I will, however, ask the local education authorities to make arrangements for observing the effect of the Summer Time Act on the health of the school children in their areas this year. But, as the honourable Member is aware, the matter is primarily one of parental supervision.

Medical News.

UNIVERSITY OF CAMBRIDGE.—Professor Frederick Gowland Hopkins, F.R.S., Fellow and Prelector in Biochemistry at Trinity College, has been elected to the newly established Sir William Dunn Professorship of Biochemistry.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The Quarterly Council was held on April 14th, with Sir Anthony Bowlby in the chair.—The President opened the envelope bearing the winning motto of the dissertation adjudged by the Jacksonian Prize Committee, and announced the winner of the prize to be Mr. Harold Burrows, F.R.C.S., of Southsea.—It was resolved that the subject for the prize for the year 1921 should be "The Effects Produced by Radium upon Living Tissues, with Special Relation to its Use in the Treatment of Malignant Disease."—A report was read from the Walker Prize Committee, dated Feb. 28th, 1921, and in pursuance of this report it was resolved that the Walker Prize for the period 1916-1920 be not awarded.—A report was read from the John Tomes Prize Committee, dated March 9th, 1921, and in pursuance of the recommendation contained in the report it was resolved that the prize for 1918-1920 be awarded to Dr. James Sim Wallace, L.D.S.—The President opened the envelope containing the motto of the essay adjudged by the Cartwright Prize Committee to be the winning essay, and announced that the winner of the medal and honorarium of £85 was Mr. W. Kelsey Fry, M.R.C.S., L.D.S.—It was resolved that the subject for the Cartwright Prize for 1921-1925 should be "Variations in the Form of the Jaws, with Special Reference to their Ætiology and their Relation to the Occlusion of the Dental Arches."—A report, dated April 7th, was read from the Examiners in Anatomy under the Conjoint Board regarding the Begley studentship, and it was resolved that in pursuance of this report Mr. Kenneth Owen Parsons, of Guy's Hospital, be appointed Begley student for the ensuing three years.—The Council, under Section 5 of the Charter of the 15th Victoria, balloted for the election to the Fellowship of the following Members of 20 years' standing: Professor Charles Scott Sherrington, P.R.S., and Sir S. Squire Sprigge.—The Council elected Mr. Raymond Johnson as the Representative of the College on the Senate of the University of London for the period from May 10th next to the second Tuesday in May, 1925, in the vacancy by the retirement of Sir Charters J. Symonds.—The secretary reported that at the last four Final Examinations for the Fellowship 243 candidates were admitted under the ordinary conditions, and that of these 156, or 64·2 per cent., failed, and that under the special war conditions 104 candidates were admitted, of whom 71, or 68 per cent., failed.—The President reported that he, Mr. H. J. Waring, Mr. R. Johnson, and Sir Cuthbert Wallace attended before the Voluntary Hospital Committee at the offices of the Ministry of Health on March 16th last and gave evidence on behalf of the College in support of the retention of the voluntary system as of great importance in the interests of the sick and of medical education.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH. ROYAL COLLEGE OF SURGEONS OF EDINBURGH, AND ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—The following candidates have passed the Triple Qualification Examination:—

THIRD EXAMINATION.

Robert W. P. Hall, James S. Allan, James A. McE. S. Evers, James M. McLintock, Henry G. F. Cubitt, Ernest Levine, Patel S. H. Masters, Alexander W. Buchan, and John M. Cockburn.

Pathology.—Helen J. Hamilton, John J. Mann, James M. Crombie and George A. P. McConey.

Materia Medica.—George F. Maher, Andrew A. Dewar, Percy A. M. Jayewardene, Bruce F. Home, Annie F. Perry, and Robert P. Anderson.

FINAL EXAMINATION.

Helen Worthington, Daniel R. Cilliers, Norman M. D. Fox, Don James H. Ferdinando, John Murray, Ardishir Jahangirji Vakil, Arnold A. Hamilton, Alan B. Taylor, Reginald E. Hopton, James I. Coventry, Ronald G. Clouston, Peter F. Fairley, Samuel Denis de Vos, Bakhtawar Singh Jain, Francis Xavier H. Hayes, John J. L. McDonald, Frederic L. A. Gace, Gilbert H. Thomas, and Krishna Abaji Deodhar.

Medicine.—Abdus Shakur, James L. Lloyd-Jones, Vincent H. L. Anthonisz, William B. Stott, William Campbell, Ram Nath Nanda, and Aflatum Yacub Khan.

Surgery.—James S. A. Rogers, Otho P. Fox, William B. Stott, and Ram Nath Nanda.

Midwifery.—Abdus Shakur, James L. Lloyd-Jones, John R. Williams, Otho P. Fox, James Pedris, Elliot P. Dewar, and Aflatum Yacub Khan.

Medical Jurisprudence.—Enid A. Williams, Thomas T. Hoskins, George H. Dobbin, Mohamed Shafia Hassen, Philip G. Bainbridge, Duncan R. Nicol, James L. Lloyd-Jones, and Rachel Caplan.

LONDON SCHOOL OF TROPICAL MEDICINE.—Sir Leonard Rogers, C.I.E., F.R.S., has been appointed extra physician for clinical research, a position which has been specially created for him; he will lecture upon subjects, such as leprosy, to which he has paid special attention.—Lieutenant-Colonel W. W. Clemesha, C.I.E. (I.M.S. retired), has been appointed lecturer on hygiene in the tropics in succession to Professor W. J. Simpson, who has recently retired. Colonel Clemesha is well known for his work upon the water-supplies of India. He has held the post of Sanitary Commissioner to the Government of India, and latterly acted as Director of Medical Services, East African Force. He is therefore well qualified to speak authoritatively upon the most recent developments of sanitary science in the tropics.

The following candidates passed the examination held at the termination of the sixty-fifth session (January-April, 1921):—

*C. T. Maitland (Duncan medal), *H. E. S. Richards, *A. Crawford, *Miss M. M. Ross, *R. G. Simpson, *J. O. Beven, *W. M. Howells, J. M. Wallace, J. Segal, O. M. Banhawy, D. N. Gore, P. Parthasarathy, M. Morrison, L. M. Sen, B. K. Ray, J. C. Rowan, H. Smith, Miss A. Shaw, D. S. Scott, R. A. W. Procter, Miss A. M. Mackay, J. C. Coetzee, K. A. Gandhi, C. L. Sahni, N. S. Kotwall, F. X. Costello, K. C. Cheng, S. Miller, P. N. Button, Miss M. Jervis, A. R. McLean, Miss L. J. Murphy, A. R. Jennings, and Miss M. J. Ahern.

* With distinction.

ROYAL MEDICAL BENEVOLENT FUND.—The annual meeting was held at 11, Chandos-street, London, W., on April 5th, with Sir Thomas Barlow, the President, in the chair. The annual report was received and adopted. It was stated that the average amount of the grants at present distributed is quite inadequate and should be considerably increased. All friends of the Fund were urged to make the wants of the Funds more widely known to their medical brethren, and to obtain new subscribers. The total amount received in donations and subscriptions was £3395 4*s.* 7*d.*, compared with £2865 3*s.* 10*d.* in the preceding year, an increase of £530 0*s.* 9*d.* The total distributed in grants during the year, including Christmas gifts made to the more urgent cases, was £2836 13*s.* 1*d.*, of which £246 9*s.* was provided from the Dinner Fund account. In the annuity department the amount this year available was £4021 1*s.* 10*d.* against £3897 9*s.* 5*d.* the previous year, an increase of £123 12*s.* 5*d.* The annuitants, who must be over 60 years of age, amount in number to 178, and in December last it was agreed to increase the amount of 38 of the pensions from £20 to £26. Grants to the amount of £5926 17*s.* 6*d.* have been made in connexion with the War Emergency Fund, and invaluable assistance has been rendered to a large number of medical men who had held commissions and found themselves on their return to practice unable to carry on without such help. The committee have already agreed to bear the cost of the education of 25 boys and girls at public schools, and they would welcome applications for such purpose on behalf of any who are eligible for help from the Fund. At present three boys are being educated at Epsom College, and the names of three more have already been entered, while the fees of 19 other children are being paid at various schools. The total amount received for the Fund amounts to £34,818 and the amount expended to £18,920. The following officers were re-elected for the ensuing year: Sir Thomas Barlow, President; Sir Charters Symonds, treasurer; and Dr. Newton Pitt, hon. secretary.

At the meeting of the committee held on April 12th 29 cases were considered, and £397 voted to 26 applicants. The following is a summary of some of the cases relieved:—

Widow, aged 67, of M.D. Dub. who practised in London and died in 1918. Applicant was left entirely without means. She has five grown-up children, but none of them are able to help her. Since the death of her husband she has paid rent, 15*s.* per week, by selling her furniture. Two sisters, now dead, used to clothe and help to support her. Voted £12 in 12 instalments.—Widow, aged 87, of L.F.P.S. Glasg. who practised in Holloway, and died in February, 1921. Applicant's husband was granted £30 in six instalments from the Fund. Applicant is now left with only the Old Age Pension, and her rent is 7*s.* per week. Voted £26 in 12 instalments.—Widow, aged 61, of M.R.C.S. Eng. who practised in Manchester, and died in 1915. Applicant asks help from the Fund owing to the recent loss of her eldest daughter through consumption, who was her chief support. Her only income is derived from letting rooms. Son only receives 9*s.* per week as an engineer's apprentice and has still another 18 months to serve. The second daughter is not working at the present time. Voted £10.—Daughter, aged 47, of M.R.C.S. Eng. who practised at Woodford and died in 1913. Applicant and sister live together; both of them are delicate and unable to work. The mother, aged 80, was an annuitant of the Fund. Since the father's death friends have collected sums of money to keep mother and sisters. This case was strongly reccommended. Voted £10 in two instalments.—Daughter, aged 54, of M.R.C.S. Eng. who practised at Redcar and died in 1873. Applicant is a trained nurse, but owing to ill-health and an operation in November last is now incapacitated. She is now dependent upon her sister, who has to earn her living as a dressmaker. Applicant is entirely without means. Voted £18 in two instalments.—M.R.C.S. Eng., aged 54, single, who practised in Liverpool and West Africa. His health was entirely undermined through living abroad, and he is quite unable to follow his profession. A brother-in-law allows him £24 per annum, and he earns about 12*s.* per week as a temporary postman. Applicant pays a portion of the rent, which is £7 16*s.* Relieved eight times, £70. Last time £10 in March, 1920. Voted £10 in two instalments.—Daughter, aged 59, of M.R.C.S. Eng. who practised at Newport (Mon.) and died in 1892. Applicant worked for 19 years as a church worker in Wales, but owing to partial blindness and internal trouble has had to give it up. The Royal United Kingdom Beneficent Association allows her £25 per annum. She also receives a little help from the Guild and a grant from the Fund for the last ten years Relieved ten times, £135; last time £18 in April, 1920. Voted £18 in 12 instalments.

Subscriptions may be sent to the honorary treasurer, Sir Charters J. Symonds, K.B.E., at 11, Chandos-street, Cavendish-square, London, W.1.

DONATIONS AND BEQUESTS.—By will the late Miss Mary Wainwright, of Croxteth-road, Liverpool, bequeathed £1200 to the Northern Hospital, Liverpool, in memory of her father, one of the founders.

THE annual dinner of the Indian Medical Service will be held at the Trocadero on Wednesday, June 15th, Major-General Sir R. Havelock Charles, G.C.V.O., in the chair. Tickets and all particulars may be obtained from the joint hon. secretary, Colonel J. J. Pratt, I.M.S. (ret.), 63, Addison-road, Kensington, W.14.

CHADWICK PUBLIC LECTURES.—Three lectures on Fevers in England: their Prevention and Control, with Special Reference to the Effects of Public Health Acts (1848-1918), will be given by Dr. William Hunter in the lecture-room of the Medical Society of London, 11, Chandos-street, on Thursdays, May 5th, 12th, and 19th, at 5.15 P.M. Admission is free.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL.—At the opening of the summer session of the Central London Throat and Ear Hospital, Gray's Inn-road, on Wednesday, May 4th, at 4 P.M., Mr. Arthur Cheatle will give a lantern demonstration on "The Cellular Development in the Temporal Bone."

TUBERCULOSIS SOCIETY OF GREAT BRITAIN AND IRELAND.—A clinical meeting of the society will be held at the Margaret-street Hospital, Margaret-street, Oxford-street, London, on Monday, April 25th, at 7.15 P.M. Cases will be shown by Dr. L. S. T. Burrell and Mr. P. Franklin, and Mr. Franklin will read a paper on Tuberculous Laryngitis, with demonstration of cases.

FEDERATION OF MEDICAL AND ALLIED SOCIETIES.—The Medical Council of this Federation at their next meeting propose to consider again pressing for a public inquiry into the conditions under which medical benefit is provided for insured persons. They will do this with special regard to supplementing the resources of the panel practitioner by providing hospital and laboratory facilities that would enable him to give efficient treatment.

HERITAGE CRAFT SCHOOLS, CHAILEY.—A festival dinner in support of these schools was held at the Savoy Hotel on April 13th, Dame Margaret Lloyd George presiding. The medical guests included Sir Robert Jones, Mr. E. Hurry Fenwick, Dr. S. Russell Wells, Sir D'Arcy Power, Dr. Graham Little, Dr. C. W. Kimmins, and Dr. William Brown. It was stated that most of the children in the schools were suffering from surgical tuberculosis. Sir Jesse and Lady Boot had presented an operating theatre, now under construction, and further arrangements for surgical and operative work were still needed. Contributions should be sent to Miss A. C. Rennie, hon. treasurer; further information can be obtained from the founder and hon. secretary, Mrs. C. W. Kimmins, the Heritage Craft Schools, Chailey, Sussex.

NEW COMMISSIONER OF PRISONS.—Dr. Sidney Reginald Dyer, Medical Inspector of Prisons, Home Office, has been appointed Commissioner of Prisons (England and Wales). Dr. Dyer was formerly medical officer of H.M. Prisons, Stafford, Wandsworth, and Brixton, and was called to the Bar at the Middle Temple in 1896.

LITERARY INTELLIGENCE.—Nippon-no-Ikai-Sha, publishers, of Tokyo, announce the appearance this month of a new medical monthly in English, entitled the *Nippon-no-Ikai*, or the *Japan Medical World*. It will contain original articles, notes on current Japanese medical literature, archives of medical societies, and medical news. The annual subscription is $6.00; single copies, $0.50, post free. Dr. S. Tsuchiya will direct the publication.

ON the resignation of Dr. Edward Walford from the appointments of medical officer of health for the city and port of Cardiff and school medical officer, he has been granted a pension or retiring allowance of £500 per annum under the superannuation clauses of the Cardiff Corporation Act, 1920. Dr. Walford had held these posts since January, 1888, his predecessor, Dr. H. J. Paine, having held office from 1847 until 1888. Thus Cardiff has had but two medical officers of health for the city in three-quarters of a century.

Appointments.

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.*

ALLAN, J., M.D., B.Ch.Edin., D.P.H., has been appointed Oculist to the Royal West of England Institution for the Deaf and Dumb.

PUNCH, A. L., M.B.Lond., M.R.C.P., Physician (in charge of out-patients), Great Northern Central Hospital, Holloway.

RICHARDSON, S. R., M.D.Dub., Assistant Medical Officer of Health for Ealing.

RUTHERFORD, MARGARET E., Assistant Medical Officer of Health to the Southend Corporation.

WALSHE, F. M. R., M.D.Lond., F.R.C.P.Lond., Assistant Physician to Out-patients to the National Hospital for the Paralysed and Epileptic, Queen-square, W.C.

WATT, J., L.R.C.P. & S.Edin. L.F.P.S.Glasg., Certifying Surgeon under the Factory and Workshop Acts for Portree.

Vacancies.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Monday, April 25th.

SPECIAL GENERAL MEETING OF FELLOWS: at 5 P.M.

MEETINGS OF SECTIONS.

Monday, April 25th.

SECTION OF ODONTOLOGY: at 8 P.M.
Paper: Mr. G. G. Campion and Mr. John Millard: Some Notes on the Growth of the Face.

Tuesday, April 26th.

SECTION OF MEDICINE.
CLINICAL MEETING at St. Bartholomew's Hospital. Tea at 4 P.M.
Cases: The following will be shown by—
Dr. George Graham: Treatment of Diabetes.
Dr. A. E. Gow: *Intravenous Protein Therapy.*
Dr. Drysdale: Splenectomy in Acholuric Jaundice.
Dr. F. R. Fraser: Digitalis Treatment by the Rapid Method.
Other cases will be shown by Members of the Hospital Staff

Thursday, April 28th.

SECTION OF UROLOGY.
At 3.30 P.M., at St. Bartholomew's Hospital:
Operations will be performed by Mr. W. Girling Ball.
At 8.30 P.M., at 1, Wimpole-street, W.:
Paper:
Mr. R. Thompson: The Treatment of Epispadias and of Extroversion of the Bladder, with Some Remarks relating to their Origin and Anatomy.
Specimens will be shown by 8.15 P.M.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.
MONDAY, April 25th.—8 P.M., Cantor Lecture (III.):—Dr. S. J. Lewis: Recent Applications of the Spectroscope and the Spectrophotometer to Science and Industry.

TUBERCULOSIS SOCIETY OF GREAT BRITAIN AND IRELAND, at Margaret-street Hospital, Margaret-street, Oxford-street, W.
MONDAY, April 25th.—7.15 P.M., *Clinical Meeting. Cases will be* shown by Dr. L. Burrell and Mr. P. Franklin. Paper:—Mr. Franklin: Tuberculosis Laryngitis, with Demonstration of Cases.

ILLUMINATING ENGINEERING SOCIETY, at the Royal Society of Arts, *John-street, Adelphi, W.C.*
TUESDAY, April 26th.—8 P.M., Discussion on Ship-lighting, in Relation to Comfort, Safety, and Efficiency, to be opened by Mr. W. J. Jones.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.
Museum Demonstrations in the Theatre of the College for Advanced Students and Medical Practitioners:—
MONDAY, April 25th.—5 P.M., Prof. Shattock: Osteoma.
FRIDAY.—5 P.M., Prof. Keith: Peritoneal Adhesions and Intestinal Stasis.

WEST LONDON POST-GRADUATE COLLEGE, *West London* Hospital, Hammersmith, W.
MONDAY, April 25th.—2 P.M., Dr. S. Pinchin: Medical Out-patients. Dr. Simson: Diseases of Women. Dr. Morton: *X Ray Department.* 2.30 P.M., Mr. Baldwin: *Visit to Surgical* Wards.
TUESDAY.—10 A.M., Dr. McDougal: Electrical Department. 2 P.M., Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. Mr. T. *Gray: Surgical Out-patients.* 2.30 P.M., Mr. Addison: Visit to Surgical Wards.
WEDNESDAY.—10 A.M., Mr. MacDonald: Genito-Urinary Department. 2 P.M., Mr. D. Armour: Visit to Surgical Wards. Mr. Sinclair: *Surgical Out-patients.* Mr. Gibb: Eye Department.
THURSDAY.—2 P.M., Mr. Baldwin: Orthopædic Department. Mr. B. Harman: Eye Department. Mr. D. Armour: Operations. 2.30 P.M., Dr. A. Saunders: Visit to Medical Wards.
FRIDAY.—10 A.M., Mr. D. Buxton: Dental Department. 2 P.M., Dr. Burnford: Medical Out-patients. Dr. Pernet: Skin Department. 2.30 P.M., Dr. Pritchard: Visit to Surgical Wards.
SATURDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 2 P.M., Dr. Owen: *Medical Out-patients.*
Daily:—10 A.M. Ward Visits. 2 P.M., In-patient, Out-patient Clinics and Operations.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
Special Intensive Course.
Daily:—10.30 A.M. and 11.45 A.M., Demonstration on *Clinical* and Laboratory Methods. 2 P.M. and 3 P.M., Groups of Illustrative Cases. 4.30 P.M., Clinical Lectures (free to medical practitioners). Lecture I.:—Monday, April 25th, Sir William Hale-White: Pleurisy. *Full Syllabus printed in Bulletin* of Fellowship of Medicine.

LONDON LOCK HOSPITAL, Harrow-road, W.
Special Course of Instruction in Venereal Disease.
MONDAY, April 25th.—2.30 P.M., Mr. Thomson: *Mode of Preparing Detoxicated Vaccines for the Treatment of* Gonorrhœa.—5 P.M., Mr. Gibbs: Complications in the Treatment of Syphilis.
TUESDAY.—2.30 P.M., Mr. McDonagh: *Symptoms and Treatment* of Metallic Intoxication. 5 P.M., Mr. Juler: Syphilitic Diseases of the Fundus, Orbit, and Ocular Muscles.
WEDNESDAY.—4.30 P.M., Mr. Joly: Treatment of Chronic Gonorrhœa in the Male.
FRIDAY.—2.30 P.M., the Pathologist: Practical Demonstration of Tests Used in Syphilis. 4 P.M., Mr. Abraham: Late Sequelæ of Gonorrhœa in the Female.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, 49, Leicester-square, W.C.
THURSDAY, April 28th.—6 P.M., Chesterfield Lecture:—Dr. W. K. Sibley: Lupus Vulgaris and Erythematosus.

INSTITUTE OF PATHOLOGY AND RESEARCH, St. Mary's Hospital, in the Lecture-room of the Bacteriological Department.
A Course of Lectures on Pathological *Research in its Relation to* Medicine, open to all Members of the Profession and Students.
THURSDAY, April 28th.—4.30 P.M., Introductory Lecture:—Sir Almroth E. Wright: Acidosis and Acidæmia, with special reference to Scurvy and Shock.

ROYAL INSTITUTION OF GREAT BRITAIN, Albemarle-street, Piccadilly, W.

Notes, Short Comments, and Answers to Correspondents.

CONGENITAL WORD-BLINDNESS.[1]

BY J. E. WALLACE WALLIN, PH.D.,
DIRECTOR, ST. LOUIS PSYCHO-EDUCATIONAL CLINIC AND SPECIAL SCHOOLS.

IN articles and books on the intelligence of mentally subnormal school children congenital word-blindness has been largely overlooked as a specific defect or as a possible factor in the pedagogical retardation of the pupils, in spite of the fact that the condition has been recognised as a nosological entity for over 40 years. The concept has remained scarcely more than an abstraction, interesting as a theory but of little practical moment, to those who have studied pedagogically retarded children by measurement of intelligence by the Binet-Simon scale or group intelligence tests. Yet analysis of individual cases shows conclusively that some children fail to advance in school chiefly because, owing to the presence of some degree of word-blindness, they are partially or totally unable to learn to read. They are thus seriously handicapped in all school work requiring mastery of printed pages; and many word-blind children, normal or merely backward in intelligence, have been diagnosed as feeble-minded and assigned to special classes for mental defectives. Illustrative cases in point have already been cited,[2] and many more could easily be added from the writer's experience. In this paper I propose to quote from an analysis made of some of the data gathered in 95 consecutive cases from St. Louis examinees whose reading disability has been attributed to visual aphasia or dyslexia.

Definition of Word-blindness.

But to explain what is meant by word-blindness—the name given by Kussmaul, who first recognised the condition in 1877,[3] does not refer to the inability to see printed or written characters, but to the inability to understand or interpret them. It is a form of asymboly which affects the imaging, remembering, and interpretation, but not the perception, of printed symbols. Word-blindness is only an instance of "mind-blindness" or "psychical blindness." In the latter condition all visual imagery is obliterated, so that no visual images or memories of any kind can be interpreted. Word-blindness may affect only letters or Arabic numerals, or certain groups of letters or figures, or certain syllables, or whole words or certain groups of words, or certain languages, but not others, or musical notes (note blindness or sensory amusia), or there may be various combinations of these symptoms; it is always accompanied by agraphia,[4] and possibly by auditory aphasia (inability to understand spoken language, attributed to a lesion in the first temporo-sphenoidal gyrus).[5] Intermittent cases have been recorded.

Lesions Connected with Word-blindness.

In the case of acquired word-blindness focal lesions have been discovered in the secondary visual area, in the angular gyrus and in the supra-marginal gyrus, in the left parietal lobe of right-handed persons. If these areas are seriously affected there is complete word-blindness. It is also believed that acquired word-blindness may result from destruction of the fibres leading from both sides of the centre of visual perception[6] (the "primary visual centre" in the posterior part of the occipital lobe) to the angular gyrus. It is assumed that lesions of congenital or hereditary origin, or lesions due to birth trauma or to injuries in early life, or an arrest of development which affect the same cerebral areas, will account for congenital word-blindness; this fact was first recognised by W. Pringle Morgan. The congenitally word-blind child cannot learn to read, or learns to read only with the greatest difficulty. A considerable difference has also been observed in the character and severity of these cases, which has led to the supposition that the more severe degrees are due to lesions or imperfections in the angular gyrus, and the lighter degrees to partial interruptions in the connecting fibres between the primary (perception) and secondary (memory) visual centres.

I shall apply the name visual aphasia to the more severe degrees and the name dyslexia[7] to the lighter degrees, employing word-blindness as the generic term.

Diagnosis.

There is no pathognomonic symptomatology of word-blindness. A differential diagnosis cannot be safely arrived at until visual defects, auditory defects, idiocy, imbecility, and possibly other as yet unrecognised conditions have been ruled out, and until the child has been given every reasonable opportunity to learn to read script and print, and has tried to do so, under the guidance of a skilled teacher. If such a child is able to name designated objects or pictures of objects, and to spell the names orally (especially short words), but is unable to pick out or recognise the corresponding names when shown in print or script, word-blindness is presumably present.

Average Age, Intelligence, &c.

The average chronological age of this group of word-blind children was 11·07, the average intelligence age 8·85 (based on the 1911 scale for 31 cases and the Stanford scale for 64), the average intelligence retardation 2·2 years, and the average intelligence quotient 80·3.

The average number of years spent in school at the time of the examination was 4·4 (counting ten months to the year), based on 88 pupils whose attendance records were available. The average grade in which the pupils were reported as doing "successful work" was 1·9, based on the available records of 44 pupils. Unfortunately, the grade in which the pupils were able to do successful work in the different branches was reported only in a limited number of cases. In reading the average successful grade was 1·8 (for 14 pupils), in spelling 2·4 (for 8 pupils), and in arithmetic 2·9 (for the same pupils as reported in reading). Reading, according to the school record, was their poorest subject. This is also shown by the reading test given in the clinic. The average time taken to read the Binet selection (54 words) and the average number of memory units reproduced for the word-blind subject, all the subjects examined in the Pittsburgh and St. Louis clinics up to August, 1917 (which we shall refer to as the subnormal group), and the epileptic children examined in New Jersey years ago,[8] who classified in the intelligence ages as indicated, are given in the following table:—

A.—Time in Seconds to Read Binet Selection. *B.—Number of Memories.*

—	Intelligence ages—								Intelligence ages—			
	VIII.		IX.		X.		XI.					
	No*	Sec.	No*	Sec.	No*	Sec.	No*	Sec.	VIII.	IX.	X.	XI.
Subnormal†	94	107·9	115	72·7	154	51·9	89	30·0	5·4	7·6	8·2	9·6
Epileptics...	11	145·1	9	85·7	22	65·3	9	31·4	3·5	4·7	6·8	6·1
Word-blind	5	162·8	5	141·2	6	130·6	2	87·0	7·0	7·8	7·1	14·0

* Number of subjects included. † The word-blind cases examined during the same period were not eliminated from this group.

It should be explained that only those subjects are included who were able to read the entire selection through, and many of them secured considerable aid from the experimenter on difficult words. All of the word-blind cases (and many of the epileptics) made numerous mistakes and were helped considerably. Even thus only 18 dyslexia cases got through the selection. Data were compiled from the dyslexia pupils who read part of the selection with aid, and the dyslexia and visual aphasia pupils who attempted to read the easiest material used in the first grade first quarter in the St. Louis schools,[9] but these results will not be referred to here. The reading selection used was that given on p. 130 of our Experimental Studies of Mental Defectives, except that the corresponding Stanford passage was used with the word-blind cases examined since September, 1917. The selections are of equal length, and probably about equally difficult.

It will be observed that the time required to read the selection by the word-blind cases is considerably longer in every intelligence age than the time required by the subjects in either of the other two groups. In age 10 it is two and a half times, and in age 11 almost three times as long as the time required by the subnormals. On the other hand, the word-blind subjects, in spite of their slowness in reading, reproduced considerably more memory units than the epileptics in every intelligence age, while they reproduced considerably more than the subnormals in age 11, slightly more in ages 8 and 9, and slightly less in age 10 only. These results are consistent with the theory that word-blindness is due to defective visual word imagery and the interpretation of such imagery and not to defective apprehension or retention of the ideas secured from printed words, provided they can be secured at all.

[3] William Broadbent had five years previously reported the condition as complicated by speech disturbances.

[4] Difficulty of writing. In the usual form monosyllables can be recognised, but longer words do not resemble the intended words. When letters cannot be formed, which is rare, the subject makes meaningless strokes, sometimes resembling stenographic or runic characters.

[5] Among the thousands of children examined only one was classified as a case of auditory aphasia; the case is described in the last reference at the end of this article. I agree with Kerr that this type of defective word imagery is exceedingly rare.

[6] From the right and left calcarine fissures.

[7] Word-amblyopia has been similarly employed by Claiborne.

[8] We have not included records of adults. See Experimental Studies of Mental Defectives, 1912, pp. 70f and 80f.

[9] Such lines as "I can run," "I am a boy," "I can play ball," "She is my little baby girl."

Absence of Visual and Auditory Defects.

The vast majority of the 85 pupils in this group, who were given a physical examination by the regular school inspectors of hygiene, did not have any significant visual or auditory defects. There were 4 cases of tinnitus and 1 of otitis media. No impairment of auditory acuity was noted. There were 2 cases of myopia, 1 of hypermetropia, 4 of astigmatism, 3 of strabismus, and 4 of conjunctivitis. We are satisfied that the word-blindness cannot be traced to physical defects in the visual or auditory sense organs in the majority, if indeed in any, of the subjects considered in this group. The defect is central. Other incidental abnormalities noted in the group include the following: chorea, 1 boy and 1 girl; infantilism, 1 boy; speech defectiveness, 7 boys and 1 girl; psychopathy, 2 boys; neurotic make-up, 3 boys and 2 girls; and conduct difficulties, 8 boys and 1 girl. It is not believed that these anomalies have any direct connexion with word-blindness.

Incidence of Word-blindness.

The incidence of word-blindness (4·48 per cent.) among the 2116 school cases examined in this series is greater than the combined incidence of epileptics, psychopaths, mongols, and cretins.[10] The large majority were examined primarily because they were thought to be mentally defective, sometimes merely because of an inability to learn to read; some of these cases proved on examination to be intellectually normal or merely slightly retarded, and others were referred primarily because of their difficulty in reading, although they were known to have had good intelligence; but we believe that the majority of pupils of fair or good intelligence who were subject to specific disability in reading were not referred, because of the necessity of restricting examination to those most defective in intelligence. For these reasons we do not venture to estimate the ratio of word-blind cases among all the St. Louis elementary school children. No accurate figures are available from other school systems. C. J. Thomas has estimated that there is one word-blind case for every 2000 boys in the London schools, but Warburg noted 14 word-blind cases among 2000 ordinary pupils in Cologne, and seven among special school children. We are convinced that if the dyslexia cases are included, the incidence of congenital word-blindness is much greater than has been thought to be the case. Of the cases we have studied, the milder form, dyslexia (3·6 per cent. of all examined, or 82·1 per cent. of the word-blind), is about five times as prevalent as the more serious form, visual aphasia (0·7 per cent. of all examined, or 17·8 per cent. of the word-blind).

Sex Incidence.

Word-blindness is apparently to some extent a sex-limited disability. In this group of cases it was about four times as prevalent among the boys as among the girls, the ratio being 5·71 per cent. for the boys and 1·47 per cent. for the girls. The writer believes he has collected the largest group of congenital word-blind cases ever presented in the literature. According to Sydney Stephenson, only 14 cases had been reported by six writers up to 1904. J. Hinshelwood, who has contributed most to our knowledge of the condition, has described a dozen cases in his latest treatise. He met with 31 congenital and acquired cases in 15 years.

The facts are not available on which to frame even a plausible explanation of the sex difference. It is suggested that visual aphasia is more prevalent than auditory aphasia, because the reading and understanding of written words was acquired much later in the history of the race than the hearing and interpretation of spoken words. But this analogical fact will not explain the sex difference found in word-blindness, because, historically, boys have probably been taught reading longer than girls. But speech defects are more frequent among boys than among girls; the difficulty in word-blindness may be traceable to the difficulty of translating a visual word or letter symbol into its appropriate auditory symbol. Although the source of the difficulty has been considered to be a defect in visual word imagery, it is possible that the seat of the trouble may be in the connexions between the centres for images for spoken words and for images for printed words. This may be indicated as an important question for investigation. Whatever the seat of the defect, the result is that the subject finds it difficult to pronounce or read the printed words. In those who cannot read words but who can copy them from the printed page the simplest explanation is to assume that the mechanism for translating the visual symbols into spoken symbols is disturbed, while the mechanism for translating the visual signs into graphic symbols is intact. There are doubtless word-blind subjects in whose case the difficulty of reading is complicated by motor aphasia, or a lesion in Broca's convolution.

Normal Intelligence in the Word-Blind.

As already pointed out, our word-blind cases as a group did not present any significant visual or auditory sense defects. Measured by the Binet "ball and field" design, and immediate memory span tests, it was determined that they were superior to the subnormal group. The tests revealed no peculiar defects in auditory or visual imagery, apart from possible defects in visual word imagery.

It had been held that the aphasias represent merely one of the intellectual disorders involving language (Adolf Meyer), and that they are accompanied by a lowering of the level of general intelligence (Wundt, Pierre Marie). On the other hand, many children subject to word-blindness have been reported to be normal in intelligence and even precocious (Hinshelwood). In practically all of such reported cases, the judgment as to the normality of the child's intelligence was based on his school report or on general impressions of intelligence, and not on standardised tests. In point of fact, our word-blind cases vary from an intelligence quotient of 54 to 104; 12 per cent. were diagnosed as normal or almost normal (retarded) in intelligence, and 85 per cent. as subnormal (the diagnosis being deferred in 2·1 per cent. of the cases). Only 5·2 per cent. were classed as feeble-minded, none of these grading lower than morons or potential morons; almost 36 per cent. were classed as backward and almost 41 per cent. as border-line. The only difference of any consequence between the visual aphasia and dyslexia cases is the greater proportion of normals among the former, which may, of course, be merely an accidental difference in this group.

Although at least 85 per cent. of our cases were subnormal in general intelligence, we are not justified in concluding that the percentage of subnormality would be equally high in an unselected group of word-blind children. Had we selected all the pupils in the schools who were conspicuously deficient in reading it is possible that the ratio of those having normal intelligence might have been higher. At any rate, the statement that there is a lowering of the general intelligence in word-blind cases cannot be sweepingly applied to all cases.

Attempted Differentiation of "Pure" Word-Blindness.

Hinshelwood has drawn a distinction between word-blindness, dyslexia, and alexia. Word-blindness represents a grave degree and dyslexia a slight degree of reading disability, due to a focal lesion in the centres mentioned above in a brain which is normal or undamaged in other areas, while alexia is applied to the condition in mental defectives who are suffering from a generalised brain defect. He holds that the symptoms of word-blindness or dyslexia must be "pure," by which he means that there must be no other accompanying symptoms of brain defects. We find no evidence whatever for any such distinction between word-blindness and dylexia on the one hand and alexia on the other hand. We have discovered no qualitative difference between word-blindness in a moron, in a borderliner, and in a normal. The differences found in word-blindness are, like those of general intelligence, differences in degree and not in kind. Intelligence varies from profound idiocy to genius; there are many grades between these extremes, but no sharp lines of demarcation can be discovered between the grades. Similarly, word-blindness varies continuously from a state of profound visual aphasia to a slight degree of dyslexia. It may eventually be possible to distinguish more groups of this disability than has yet been done, but there will be no gaps between the groups; the nature of the fundamental reading disability will probably be the same whether or not the symptoms are "pure"; the differences will be quantitative and not qualitative. It would, of course, be meaningless to speak of an imbecile as subject to word-blindness, because the highest grade of imbecile merely approaches the bottom of the curve of capacity in reading; but our records clearly show that the highest grades of the feeble-minded (the so-called low-grade morons) are subject to the same kind of reading disability as pupils who are merely backward or normal in intelligence. Like the latter, they do distinctly poorer work in reading (and often in spelling as well) than in many other school subjects.[11] But no qualitative difference has been discovered between the reading disability of the word-blind mental defective and the word-blind backward or normal child.

[11] For illustrative cases other than those given in this article the writer's references to my contributions in the bibliography

A Neurological Parallel.

On the neurological side parallel differences will probably be found. Different brains will show many degrees of soundness, perfection, or defectiveness involving different areas. Various degrees of fineness in structural organisation probably exist in many areas of the brain in most persons. The existence of multiple imperfections would complicate and aggravate the word-blindness, but it would not produce a different kind of word-blindness. Reading disability is due to word-blindness when there is a defect in the secondary visual centre concerned with the imagery of words or in the connecting fibres between the secondary and primary visual centres, whether or not the symptoms are "pure."

Conclusion.

To conclude with a practical point, word-blind children who are not feeble-minded should be assigned to special reading disability classes, where various methods and devices of teaching reading may be tried. We shall find that some children will be reached by some methods, others by other methods, but when it has been shown that a child *cannot be taught to read by the intensive application of* various methods, teaching should be given orally. In fact, one of the advantages of assigning a word-blind child to a reading disability class is that he may secure from the teacher's lips the instruction which fits his level of intelligence and which he cannot secure through the printed page because of his inability to read. The usual practice is to assign word-blind pupils to ungraded classes or special schools or to place them in the first grade. But in such classes the teachers must ordinarily teach so many subjects that they cannot specialise on reading. Moreover, even if large use is made of the oral method of presentation, the instruction may not meet the child's intellectual needs. The oral instruction in a first grade or in a school for mental defectives would not fit the intellectual level of a word-blind but intellectually normal child of 10. His reading and intellectual needs can only be met in a properly conducted reading-disability class. We have frequently urged the establishment of an experimental class of this type in St. Louis, but the financial difficulties confronting the schools have prevented any action being taken in the matter.

EUGENICS v. CIVILISATION.

ON April 12th, under the above title, Mr. F. C. S. Schiller, D.Sc., delivered a lecture at the rooms of the Royal Society, on behalf of the Eugenics Society. Eugenics, he said, as a science was a study of the conditions of improvement of the human race; but improvement *meant making better*, and that implied a standard of good. Civilisation, which was an achievement of man and not a congenital quality like, for instance, sex, also implied a standard of good. A baby born of civilised parents had to acquire civilisation: it had to be impressed upon the child by training, and if subsequently the individual liked civilisation it was an acquired taste. The transmission of civilisation in the social order was effected in very complex ways, and were the mechanism of this transmission to be destroyed or seriously damaged civilisation would disappear in one generation, as would probably be the case in Russia. It was often regarded as a fatal objection to eugenics that what would be the best type of man was not known, and therefore could not be produced. Though there was truth in this objection, a knowledge of what was good was equally involved in the notions of progress and of civilisation. The eugenist at least knew enough to deplore the suicidal organisation of our present civilisation, which was arranged so as to eliminate not only the qualities which were good but even those thought to be good, and so was ruining the human race. The reason was that in all civilised societies the birth-rate was relatively high in the lower social strata, and so low in the higher that it had to be recruited from the lower. As social promotion was everywhere the reward of merit—of the qualities a society valued and regarded as good—and as social structure was now less rigid than in the past, merit rose more easily than formerly. This promotion, however, meant inclusion in a class in which the numbers were halved in each generation. This recognition of merit was also biologically its capital punishment, and civilisation was actually extirpating the very qualities it considered valuable. The organisation of society at the present moment must be pronounced apallingly dysgenic, it had become an instrument of deterioration of the human race, and if progress was still being made it was being made in the mechanism by which the world was controlled, which was quite independent of what was good. This dysgenic effect of civilisation was no new thing, though it was now probably proceeding faster than formerly; it explained why aristocracies always died out, why the physical development of the human race had been arrested, and why there was no reason to think that modern races were mentally superior to the ancients. Militarism tended to eliminate itself. All through history the fighting races had fought themselves to extinction and all through history the meek had inherited the earth. There had been going on in every community an internal selection which might profoundly change the ideas and type of the people.

Retrogressive Brain Development in Man.

The bodily development of man had long ago come to a standstill. There had been no improvement in the human type since the beginning of history, nor was there reason to think that man was intrinsically more intelligent. Brain development had apparently been retrogressive for a long time, and it was a mere assumption that we use smaller and more compact brains more efficiently. The only power which man had developed was a resistance to microbic disease. It was a mistake to think that intelligence was not an important factor in savage life. The savage could not afford to be a fool or to breed fools, and in the ordinary affairs of life he was far more capable of fending for himself than those who disparaged him. Nor was he more helpless in the City of London than a bank clerk on a primitive island, or a professor in a jungle. In savage life the fool and idiot could not grow up to leave behind an adult brain. The human stock must at one time have been progressive, or else it would never have developed out of the ape. It was still progressive wherever social conditions conduced to a preferential survival of the better portions of the stock rather than of the worse. This occurred among savages subjected to severe natural selection, so that weaklings could not be preserved. This also occurred among barbarians where the well born were more prolific than the lower classes. It could occur in civilised societies if they recognised the error of their ways and the need of thorough-going eugenic reform. The recognition of the race-deteriorating tendency of civilisation was a new and important fact, but once recognised it could be counteracted by a variety of expedients, which, though difficult, were not impracticable. As for the theoretical difficulty that we did not know precisely what were the good types to be preferred, it was essentially nugatory. In a general way the good could be discriminated from the bad, and by cautious experiments the bad could be further eliminated.

PUBLIC HEALTH OF ST. VINCENT.

THE Registrar-General's estimate of the population on Dec. 31st, 1919, was 53,210. The birth-rate for the year was 24·8, and the death-rate 20·67 per 1000. Illegitimate births were 68·1 per cent. of the total births. The general health continued to be good throughout the year. *Rain fell on 203 days in 1919, the greatest fall* for one day being 3·61 inches on August 23rd.

"THIS CONCERNS *YOU.*"

THIS is the title of a pamphlet by Dr. S. G. Moore, medical officer of health for Huddersfield (London: The St. Catherine Press. Pp. 16. 2*d.*), who states in a sub-title that it was written for the Honourable Nathan Straus, of New York. It is a warning of the "danger which lurks in raw milk," and a plea for the universal adoption of pasteurisation. Detailed directions are given for home pasteurisation, but though the mother of an artificially-fed infant is advised not to pour the milk into another vessel, but to let the child feed from the bottle in which it comes, no illustration is given of a type of nipple which would convert the milk bottles illustrated into suitable feeding bottles. Moreover, the section of advice to mothers is self-contradictory, since in the second paragraph the mother is enjoined to feed the child every three hours during the first month, whereas further down on the same page the appropriate food for the first month is said to be eight 3 oz. bottles a day, one every two and a half hours. However, any effort to bring home to the public the need for pure milk, whether on antiseptic or on aseptic principles, should be commended, and Dr. Moore defines what he means by pasteurisation in the March number of *National Health.*

LIBRARY

A Report
UPON 25 CASES OF
ACTINOMYCOSIS,
WITH ESPECIAL REFERENCE TO VACCINE THERAPY.
A DISCUSSION OF SOME PROBLEMS CONNECTED WITH THE DISEASE.

BY LEONARD COLEBROOK, M.B., B.S.LOND.,
ASSISTANT, BACTERIOLOGICAL DEPARTMENT, NATIONAL INSTITUTE FOR MEDICAL RESEARCH, HAMPSTEAD.

IN a previous communication[1] I have described the mycelial and other micro-organisms met with in investigating a series of cases of human actinomycosis, most of which were under treatment at the Inoculation Department, St. Mary's Hospital, during the years 1911–15. A clinical account of several of the cases has already been published by Mr. V. Z. Cope,[2] who originally sent them to the Inoculation Department and afterwards collaborated with Sir Almroth Wright in the direction of their treatment. (Mr. Cope's paper also gives a valuable clinical account of the actinomycotic infections in general.)

In the present communication it is proposed to record what was learned from this series of cases in respect of the diagnosis, the clinical course, and particularly the treatment of the disease; and subsequently to discuss two questions which arise—viz., What is the source of these infections? and What restrictions is it advisable to put upon the use of the term actinomycosis?

Definition.—The cases here dealt with all presented granulomatous lesions from which the so-called "sulphur granules," visible to the naked eye, were forthcoming, and these granules were in every case composed of a feltwork of Gram-staining mycelium. The importance of strictly limiting the use of the terms actinomycosis (and paractinomycosis) to cases of this kind will be discussed later.

Diagnosis.—We have at present no reliable method of detecting an actinomycotic infection in its early stages—i.e., prior to the occurrence of suppuration. The slowly progressive, comparatively painless, and indurated lesion may suggest the diagnosis, but one is at a loss to confirm it by blood examinations, for opsonic estimations will often fail to distinguish between a tuberculous and an actinomycotic infection (the opsonic power to the tubercle bacillus is frequently high in actinomycosis), and agglutination tests with actinomyces, although they will usually give positive results in advanced cases, are apt to be negative in the milder cases. Further observations on this latter point are required.
